(Received 24 January 2019; published 25 October 2019)

The determination of the primary energy of extensive air showers using the fluorescence detection technique requires an estimation of the energy carried away by particles that do not deposit all their energy in the atmosphere. This estimation is typically made using Monte Carlo simulations and thus depends on the assumed primary particle mass and on model predictions for neutrino and muon production. In this work we present a new method to obtain the invisible energy from events detected by the Pierre Auger Observatory. The method uses measurements of the muon number at ground level, and it allows us to significantly reduce the systematic uncertainties related to the mass composition and the high energy hadronic interaction models, and consequently to improve the estimation of the energy scale of the Pierre Auger Observatory.

DOI: [10.1103/PhysRevD.100.082003](https://doi.org/10.1103/PhysRevD.100.082003)

I. INTRODUCTION

The flux of cosmic rays with energy above 10^{15} eV is so tiny that the only way to study it is to detect the extensive air showers that primary cosmic rays produce in the Earth's atmosphere. This is typically done using arrays of particle detectors on the ground. The estimation of the shower energy is one of the most challenging problems because the conversion of the signal detected at ground level into shower energy needs detailed Monte Carlo simulations of the air showers which are subject to large uncertainties. In fact, the signal detected at ground level depends on the primary mass which is unknown, and on details of the hadronic interactions which are also unknown, because the interactions are at energies and in phase-space regions not well covered by, or not accessible to, accelerator experiments.

Above 10^{17} eV, the problem of energy estimation has been solved with the implementation of the fluorescence detection technique. A fluorescence telescope detects the fluorescence radiation emitted by the nitrogen molecules of air excited by the charged particles of the shower. The fluorescence radiation is produced in proportion to the energy dissipation, allowing a reconstruction of the longitudinal profile of the energy deposit (dE/dX) of the shower as a function of the atmospheric depth (X). Thus, with the fluorescence detection technique, the atmosphere is used as a calorimeter, and the integral $\int (dE/dX)dX$ is called the calorimetric energy of the shower (E_{cal}). Here, E_{cal} underestimates the total shower energy (E_0) because neutrinos do not suffer electromagnetic interactions, and high energy muons reach ground level after releasing only a portion of their energy into the atmosphere. Thus, an estimation of the primary energy E_0 with the fluorescence detection technique is obtained by adding to E_{cal} a correction to

account for the *invisible* energy (E_{inv}) carried by the particles that do not dissipate all their energy in the atmosphere. Note that E_{inv} , sometimes also called *missing* energy in the literature, was calculated for the first time by Linsley [1], and it amounts to about 10%–20% of the total shower energy.

The fluorescence detection technique has been successfully implemented in the Fly's Eye experiment [2] and its successor the High Resolution Fly's Eye (HiRes) [3]. The Fly's Eye group used a parametrization of E_{inv} derived from the estimation of Linsley [4]. Later, a more refined calculation of E_{inv} was presented in [5]. In that work the invisible energy was calculated using simulated showers. The method consisted of subtracting from E_0 the calorimetric energy calculated from the number of charged particles as a function of atmospheric depth and assuming a mean energy loss rate.

Profiting from improvements in the detail of air shower simulations, a different and better approach to calculate E_{inv} was presented in [6]. The strategy consisted of obtaining E_{inv} directly from the energy deposited in the atmosphere by the different components of air showers. This method has been used to estimate the shower energy with the fluorescence detection technique by the two largest cosmic ray observatories currently in operation: the Telescope Array (TA) [7] and the Pierre Auger Observatory (Auger) [8].

Despite the more precise calculation developed in [6], the invisible energy estimate is affected by the irreducible uncertainties associated with the models describing the hadronic interactions. While there have been some significant improvements in these models, in particular, for the first interaction at high energy for which the inelastic cross section and multiplicity have been severely constrained by LHC results [9], the neutrino and muon production still suffers from the fact that the particle identification in accelerator measurements is poorly constrained in the

* auger_spokespersons@fnal.gov; <http://www.auger.org>

phase space relevant to air shower development. After the introduction of the forward ρ^0 resonance in all models [10], the differences between the predictions for the muon content have been reduced significantly, but independent measurements still show that all models suffer from a deficit of muon production compared with data [11].

The uncertainty in the total shower energy due to the invisible energy model is not expected to be very large because E_{inv} is only a modest fraction of E_0 . For example, in [6] the uncertainty in E_{inv} propagated to E_0 was estimated to be about 5%. The models to get E_{inv} can be improved further using the primary mass composition estimated with the fluorescence detectors [12]. However, we should keep in mind that the uncertainties associated with the hadronic interaction models are difficult to estimate and are ultimately unknown [9].

In this paper we present a new estimate of the invisible energy obtained by analyzing the data collected by the Pierre Auger Observatory [8]. The estimation is done by exploiting the sensitivity of the water-Cherenkov detectors (WCD) of Auger to shower muons. We have developed two different analysis methods for two different ranges of zenith angles of the showers [13,14]. In both cases, our data-driven estimation of the invisible energy allows us to significantly reduce the dependence on mass composition and hadronic interaction models.

The paper is structured in the following way. In the first section we briefly describe the Auger detectors, while the second section deals with the phenomenology of the invisible energy, addressing the basic features of air shower development that will allow us to obtain the data-driven estimation of E_{inv} . Next, we describe the analysis methods, and we report the results of the estimation including the systematic uncertainties. Finally, we discuss the results and report the conclusions of this work.

II. THE PIERRE AUGER OBSERVATORY

The Pierre Auger Observatory [8] is located in a region called Pampa Amarilla, near the town of Malargüe in the province of Mendoza (Argentina), at $\sim 35^\circ$ S latitude and an altitude of 1400 m above sea level. Auger is a *hybrid* observatory because the measurements are done by combining the data of a surface detector (SD) and a fluorescence detector (FD). In this way, the tiny flux of the ultrahigh energy cosmic rays can be studied with the 100% duty cycle of the SD and with the precise shower energy estimation of the FD. The calibration of the SD signals against the FD energies is done by analyzing the subset of showers detected simultaneously by the two detectors, the so-called hybrid events.

The SD consists of 1660 WCDs arranged on a hexagonal grid of 1.5 km spacing extending over a total area of ~ 3000 km². Each WCD unit is a plastic tank of cylindrical shape, 10 m² in area and filled to a depth of 1.2 m with purified water. The Cherenkov radiation produced in the

water is detected by three photo-multiplier tubes (PMTs), each 9" in diameter. The PMT signals are digitized by flash analog-to-digital converters (FADC) at a 40 MHz sampling rate and calibrated online continuously using the signals produced by atmospheric background muons.

The FD consists of 24 telescopes placed in four sites located along the perimeter of the Observatory that overlook the atmosphere above the surface array. Each telescope has a field of view of $30^\circ \times 30^\circ$ and is composed of a spherical mirror with a curvature radius of 3.4 m and a camera, placed on the focal surface, which has an array of 440 hexagonal pixels (22 rows $\times$ 20 columns) each equipped with a light concentrator and a PMT. The PMT signals are digitized by an ADC at a frequency of 10 MHz. The FD operates during clear and moonless nights with a duty cycle of about 14% [15].

The WCDs are sensitive to the electromagnetic and hadronic components of a shower. Electrons and photons are absorbed in the water and produce Cherenkov light in an amount approximately proportional to their energy, while muons produce a signal proportional to their track length. Thanks to the 1.2 m height of the WCDs, the array is also sensitive to showers arriving at large zenith angles. In these showers, the signals detected by the WCDs are dominated by muons because the electromagnetic component of the shower is largely absorbed during the long atmospheric depth traversed before reaching ground level.

Two different reconstruction techniques are used for the events recorded by the SD: one for the so-called vertical showers with zenith angles $\theta < 60^\circ$ and one for the inclined showers with $\theta > 60^\circ$. In vertical showers, the energy estimator is $S(1000)$, the signal at 1000 m from the core [8]. In inclined showers, the energy estimator is the normalization of simulated muon density maps that are used to predict the muon pattern at ground level [16].

For the FD events, the reconstruction of the energy deposit dE/dX as a function of atmospheric depth is described in [15]. It is fitted with a Gaisser-Hillas [17,18] function whose integral gives the calorimetric energy. The total shower energy is obtained by adding the invisible energy correction. The FD is also used to set the energy scale of the Observatory, which is known with a systematic uncertainty of 14% [19]. In addition, the FD measures the depth X_{max} at which dE/dX reaches its maximum since it is the main experimental observable used to estimate the primary mass composition [20].

III. PHENOMENOLOGY OF THE INVISIBLE ENERGY

The basic features of the development of the extensive air showers produced in the Earth's atmosphere by primary nuclei are described by the Heitler model [21] and its extension to the hadronic case [22]. Although simplified in several aspects, this model allows a description of the cascade which is suitable enough to serve as a guiding

thread in the next sections, where the starting points of the data-driven approaches to estimate E_{inv} will be inspired by some of the expressions outlined below.

In the model, only pions are produced in the hadronic interactions (in the proportion of two charged pions for every π^0), and they all have the same energy. The particle multiplicity (N) is assumed to be the same at all energies and in all interactions. The neutral pions decay almost immediately into two photons, generating an electromagnetic cascade. The charged pions interact hadronically until the average energy of the charged pions is decreased to such a level that their time-dilated decay length (λ_d) becomes smaller than their hadronic interaction length (λ_i). This energy is referred to as the pion critical energy, and it is given by

$$\epsilon_c^\pi = \frac{E_0}{N^n}, \quad (1)$$

where E_0 is the primary particle energy and n is the number of interactions suffered by the charged pions. Note that n can be determined from the equation $\lambda_i = \lambda_d = \rho \epsilon_c^\pi \tau_\pi / (m_\pi c)$, where ρ is the atmospheric density, τ_π is the pion lifetime, and m_π is its mass. As pointed out in [23], for an isothermal atmosphere $\rho \propto \lambda_i n$, and this equation becomes

$$n \epsilon_c^\pi = \frac{h_0 m_\pi c^2}{\cos \theta c \tau_\pi}, \quad (2)$$

where h_0 is a constant and θ is the zenith angle of the shower. Then, combining Eq. (1) and (2), one arrives at the interesting conclusion that both n and ϵ_c^π depend only on N , E_0 and θ , and they do not depend on the interaction length [23]. The model provides numerical values of ϵ_c^π of a few tens of GeV with a slow decrease with E_0 [23].

One important feature of the model is that the invisible energy is proportional to the number of muons N_μ reaching ground level. In fact, once the pions reach ϵ_c^π , they decay into muons and neutrinos that are assumed to reach ground level without any interaction (the model neglects muon decay). Then the invisible energy is simply given by

$$E_{\text{inv}} = \epsilon_c^\pi N_\mu, \quad (3)$$

where the number of muons is equal to the number of charged pions [$N_\mu = (\frac{2}{3}N)^n$]. This expression will be the guiding thread to estimate E_{inv} with inclined showers, for which a measurement of N_μ is possible.

Another important feature of the model is that the invisible energy follows a power-law relationship with the primary energy:

$$E_{\text{inv}} = \epsilon_c^\pi \left(\frac{E_0}{\epsilon_c^\pi} \right)^\beta, \quad (4)$$

where $\beta = \ln(\frac{2}{3}N) / \ln N$. Air shower simulations predict values of β in the range from 0.88 to 0.92 [23], which correspond to values of N between 30 and 200. Note that β also fixes how the invisible energy depends on the mass number A of the primary. In fact, neglecting collective effects in the first interactions so that the cascade is the superposition of A cascades initiated by primary protons of energy E_0/A , one has

$$E_{\text{inv}}^A = \epsilon_c^\pi \left(\frac{E_0}{\epsilon_c^\pi} \right)^\beta A^{1-\beta}. \quad (5)$$

This is the other relationship that will be used to estimate E_{inv} from the Auger data, as it will be the guiding thread for the analysis of the vertical showers.

The Heitler model [21] extended to the hadronic case [22] described above provides a qualitative description of the shower cascades. For more quantitative predictions one has to use Monte Carlo simulations that take into account all the complex phenomena occurring throughout the shower development. The invisible energy of the simulated showers is calculated following the method described in [6]. Here, E_{inv} is obtained by subtracting from the primary energy E_0 all the energy deposited into the atmosphere. The calculation counts as deposited energy the energy that would have been deposited into the atmosphere by particles whose interactions are not simulated because they have reached ground level or because their energies are below a predefined threshold that is set to reduce the CPU time needed to simulate the shower.

This E_{inv} definition is well suited for the fluorescence reconstruction technique, given that the calorimetric energy is estimated by integrating the Gaisser-Hillas profile over all depths, including those below ground level.

The correlation between E_{inv} and N_μ has been studied by simulating showers with the CORSIKA [24] code. The results of the simulations for different primary masses and for the most recent hadronic interaction models EPOS LHC [25], QGSJetII-04 [26] and Sibyll2.3c [27] tuned with LHC data and the older models EPOS 1.99 [28], QGSJetII-03 [29], QGSJet01 [30] are shown in Fig. 1. The simulations refer to primaries of energy 3×10^{18} eV with a zenith angle of 60° , and N_μ is obtained by counting all muons with energy greater than 100 MeV that reach ground level at the altitude of the Observatory.

A variety of models have been used to cover different physics processes at the origin of the muon production. According to [22], the total multiplicity and the pion charge ratio (which is linked to the baryon and ρ^0 resonance production [31,32]) are two fundamental parameters that drive the production of muons in air showers. As a result, a model with a low baryon production and low multiplicity like Sibyll 2.1 [33] (a version of Sibyll before the advent of the LHC data) has the lowest muon number, while after correction Sibyll 2.3c now has the largest muon number.

FIG. 1. Correlation between the invisible energy and the number of muons reaching ground level for primaries of different masses, all with energy of 3×10^{18} eV.

QGSJet01 has a relatively large muon production because of its high multiplicity and despite the lack of ρ^0 resonance production. The difference between QGSJet-03 and QGSJet-04 in regard to the muon production is mostly in the ρ^0 production, while the difference between EPOS 1.99 and EPOS LHC is mostly due to a change in the forward baryons in high energy interactions.

In spite of the different implementations of the physics processes that lead to a very large spread in the predictions of N_μ and E_{inv} , the correlation between them is good and is similar for all models and primaries considered. This suggests that it is possible to obtain a robust estimation of E_{inv} from the measurements of N_μ using the Auger inclined showers.

Other quantitative predictions of the values of E_{inv} using Monte Carlo simulations are shown in Fig. 2. The results are presented, showing the ratio of the invisible energy to the total primary energy as a function of E_{cal} . The simulations were performed using the CORSIKA [24] code for the models EPOS 1.99 [28] and QGSJetII-03 [29] and with the AIRES [34] code for QGSJet01 [30] (left panel). For the models tuned with the LHC data EPOS LHC [25], QGSJetII-04 [26], and Sibyll2.3c [27], we used the CONEX code [35] (right panel).

From the figure one can see the large differences in the values of E_{inv} for different primary masses and how, for a given primary mass, the spread between the predictions from different models is significantly reduced after the tuning with LHC data. Then one may argue that a precise estimation of E_{inv} can be obtained using the post-LHC models and the primary mass composition estimated from the X_{max} measurements [20]. However, even after the updates with LHC data, the models still fail to describe the muon density at ground level [16,36,37], which can introduce unpredictable biases in the E_{inv} estimation.

Thus, the strategy followed in this paper is to estimate the invisible energy using the correlations that exist between E_{inv} and shower observables that can be measured at the Observatory, correlations that to a large extent are not sensitive to the hadronic interaction models and primary mass composition.

IV. ESTIMATION OF INVISIBLE ENERGY USING AUGER DATA

The most straightforward way to estimate the invisible energy using Auger data is to use the inclined showers. In fact, for these showers it is possible to measure the total number of muons arriving at ground level which is, as seen in Sec. III [Eq. (3)], an observable expected to be

FIG. 2. Average invisible energy fraction as a function of the calorimetric energy calculated with Monte Carlo simulations using the hadronic interaction models tuned with LHC data (right panel), and the older models developed when the LHC data were not available (left panel). The predictions for proton and iron primaries are shown with solid and dashed lines, respectively.

proportional to E_{inv} with a proportionality factor only marginally dependent on hadronic interaction models and primary mass.

The muon number cannot be directly measured for vertical events. However, the invisible energy can be obtained from the energy estimator using the power-law relationship between E_{inv} and the total shower energy [see Eq. (5)].

A. E_{inv} from inclined showers

The reconstruction of inclined events is described in [16]. The basic information used in the reconstruction is that the muon number distribution at ground level can be described by a density scaling factor that depends on the shower energy and primary mass, and by a lateral shape that, for a given arrival direction (θ, ϕ) of the shower, is consistently reproduced by different hadronic interaction models and depends only weakly on the primary energy and mass. The muon number density as a function of the position at ground $\vec{r}$ is then parametrized with

$$\rho_{\mu}(\vec{r}) = N_{19} \rho_{\mu,19}(\vec{r}; \theta, \phi), \quad (6)$$

where $\rho_{\mu,19}(\vec{r}; \theta, \phi)$ is a reference distribution conventionally calculated for primary protons at 10^{19} eV using the hadronic interaction model QGSJetII-03 [29], and the scale factor N_{19} represents the shower size relative to the normalization of the reference distribution.

The scale factor is determined with a maximum-likelihood method based on a realistic Geant4 [38] simulation of the WCD response. The simulation is done with the Auger Offline software framework [39]. A residual electromagnetic signal component, mainly due to muon decays in flight, is taken into account according to model predictions [40].

The performance of the reconstruction is validated on simulated events. For each event, the reconstructed value of N_{19} is compared with its true value R_{μ}^{MC} . The latter is defined as the ratio of the total number of muons at ground level to the total number of muons in the reference model. The relative deviation of N_{19} from R_{μ}^{MC} is within 5% for several hadronic interaction models and primaries [37]. A bias correction is then applied to N_{19} in order to reduce the residuals to within 3% of the most recent models tuned with LHC data. In this way, the corrected value of N_{19} , which in the following is called R_{μ} , represents an unbiased estimator of the total number of muons at ground level.

The correlation between the invisible energy and the total number of muons at ground level is studied with Monte Carlo simulations. Two data sets are simulated: one with CORSIKA [24] using the hadronic interaction models EPOS LHC [25] and QGSJetII-04 [26] and the other with AIRES [34] using the model QGSJet01 [30]. The showers have zenith angles isotropically distributed between 60° and 80° and energies ranging from 10^{18} to 10^{20} eV.

For each Monte Carlo event, we calculate the values of E_{inv} and of the muon number at ground level R_{μ}^{MC} . For all the samples of simulated events, the correlation between E_{inv} and R_{μ}^{MC} is well described by a power-law functional form

$$E_{\text{inv}} = C(R_{\mu}^{\text{MC}})^{\delta}, \quad (7)$$

where the values of the parameters C and δ are obtained from a fit to the events. Examples of the correlation between E_{inv} and R_{μ}^{MC} are shown Fig. 3, where the lines show the fitted power-law relationships. For all simulations, the root mean square of the distribution of residuals of the fit is less than 10%. The values of the parameters for all the simulations are shown in Table I. All the values of δ

FIG. 3. Correlation between E_{inv} and R_{μ}^{MC} for the proton (black dots) and iron (grey dots) showers simulated with the EPOS LHC [25] (left) and QGSJetII-04 [25] (right) hadronic interaction models. The red and blue lines are the results of the fit of the power-law parameters [Eq. (7)] for protons and iron, respectively. For a better visualization of the data, E_{inv} has been multiplied by the factors shown in the figure.

TABLE I. Values of the parameters describing the power-law relationship between E_{inv} and R_μ^{MC} [Eq. (7)] for proton and iron primaries and different hadronic interaction models.

Primary and hadronic interaction model		C [10^{18} eV]	δ
Proton	EPOS LHC [25]	0.739	0.967
	QGSJetII-04 [26]	0.732	0.956
	QGSJet01 [30]	0.736	0.969
Iron	EPOS LHC [25]	0.816	0.967
	QGSJetII-04 [26]	0.801	0.951
	QGSJet01 [30]	0.810	0.963

are close to 1, showing the validity of the prediction done by the Heitler inspired model [22] according to which the invisible E_{inv} is proportional to N_μ [see Eq. (3)].

The relationship of Eq. (7) is used to estimate the invisible energy in the data from the measurement of R_μ that, as seen before, is the unbiased estimator of R_μ^{MC} . Since the primary mass composition of the data is not precisely known, the estimation of the invisible energy is obtained using the parametrization of E_{inv} as a function of R_μ for a mixture of 50% protons and 50% iron. This is done by taking the average of the two E_{inv} estimations that are obtained for proton and iron primaries using the EPOS LHC [25] hadronic interaction model.

The performance of the analysis is studied on fully simulated events for which the detector response is simulated with the same method used to estimate the bias in N_{19} [37] and R_μ is reconstructed with the same algorithm used for the data. For each simulated event, we compute E_{inv} from R_μ using the estimation for the mixed proton and iron composition, and we compare it with the true value of the invisible energy. The average values of the residuals as a function of the true value of E_{inv} are shown in Fig. 4 for all primaries and hadronic models of Table I. The residuals are within $\pm 10\%$, which is an indication of the overall systematic uncertainty in the E_{inv} estimation, which is dominated by the model and mass composition dependence of the values of C and δ .

B. E_{inv} from vertical showers

As seen in Sec. III, the invisible energy depends on primary energy through a power-law relationship

$$E_{\text{inv}} = \epsilon_c^\pi \beta_0 \left(\frac{E_0}{\epsilon_c^\pi} \right)^\beta. \quad (8)$$

The parameter β_0 , equal to $A^{1-\beta}$ in the Heitler model extended to hadronic cascades [22] [see Eq. (5)], has been introduced in order to account for the large variations in the predictions of the number of muons that are obtained using different hadronic interaction models once the shower energy and primary mass are fixed.

In the reconstruction of vertical events, the primary energy is estimated from $S(1000)$ by correcting for the

FIG. 4. Average value of the relative difference between the reconstructed value of E_{inv} obtained with the EPOS LHC [25] parametrization for a mixture of 50% proton and 50% iron inclined showers.

shower attenuation using the constant intensity cut method [41]. To estimate E_{inv} from $S(1000)$, we use the functional form

$$E_0 = \gamma_0(\Delta X) [S(1000)]^\gamma, \quad (9)$$

where $\Delta X = 875 \text{ g/cm}^2 / \cos \theta - X_{\text{max}}$ is the atmospheric slant depth between ground level and the depth of the shower maximum development (875 g/cm² is the vertical atmospheric depth of the Auger site, θ is the zenith angle of the shower), and $\gamma_0(\Delta X)$ is related to the attenuation of $S(1000)$ with ΔX . In contrast to the relationship used to get the SD energies, the dependence of E_0 on ΔX allows us to better take into account the shower-to-shower fluctuations and thus obtain a more precise estimation of E_{inv} .

Combining Eqs. (8) and (9) one obtains

$$E_{\text{inv}} = \epsilon_c^\pi \beta_0 \left(\frac{\gamma_0(\Delta X) S(1000)^\gamma}{\epsilon_c^\pi} \right)^\beta \quad (10)$$

$$= A(\Delta X) [S(1000)]^B, \quad (11)$$

where

$$A(\Delta X) = (\epsilon_c^\pi)^{1-\beta} \beta_0 [\gamma_0(\Delta X)]^\beta, \quad (12)$$

$$B = \gamma\beta. \quad (13)$$

The parameter B and those defining the function $A(\Delta X)$ are determined using Monte Carlo simulations. Using the QGSJetII-03 hadronic interaction model, we find $\beta = 0.925$ and $\gamma = 1.0594$, so their product is $B = 0.98$. We have verified that different interaction models yield the

same value of B to within 2%. This value will be used from now on, so with Eq. (11) and the measurements of $S(1000)$ and ΔX , one can obtain an event-by-event estimate of E_{inv} .

The function $A(\Delta X)$ is calculated using Monte Carlo simulated events in which the WCD is simulated with Geant4 [38] using the Auger Offline software framework [39]. The simulations are done with the QGSJetII-03 [29] hadronic interaction model for a mixed composition of 50% protons and 50% iron. Note that $A(\Delta X)$ is parametrized with the fourth-degree polynomial reported in the Appendix A.

The performance of the analysis is tested with Monte Carlo proton and iron events simulated with the hadronic interaction models QGSJetII-03 [29] and EPOS 1.99 [28] and using the Offline framework to simulate the detector response. Here, E_{inv} is calculated from $S(1000)$ and ΔX and compared with the true invisible energy. The average values of the residuals as a function of the total shower energy are shown in the left panel of Fig. 5 and are between -5% and 20% . The spread in the residuals is mainly due to the difference in the predictions of the number of muons and of the attenuation function $\gamma_0(\Delta X)$ among the simulations used to parametrize $A(\Delta X)$ and the ones used to simulate the events. We note that the function $\gamma_0(\Delta X)$ includes the conversion factor needed to obtain the shower energy from $S(1000)$, which is strongly model dependent.

A better estimation of E_{inv} can be obtained by taking into account these differences using the following equation:

$$E_{\text{inv}} = A(\Delta X)[S(1000)]^B \left(\frac{\tilde{\gamma}_0(\Delta X)}{\gamma_0(\Delta X)} \right)^\beta \frac{\tilde{\beta}_0}{\beta_0}, \quad (14)$$

where the quantities with and without the accent tilde are calculated for the data sample that we are analyzing and for the one used to parametrize $A(\Delta X)$, respectively. Here, β is fixed to 0.925. The functions γ_0 are obtained from Eq. (9) using the shower energy and $S(1000)$. The ratio $\tilde{\beta}_0/\beta_0$ is estimated from the ratio of the number of muons at ground level for the two data sets, information that is available in the CORSIKA events. The residuals in E_{inv} using the improved parametrization of Eq. (14) are shown in the right panel of Fig. 5. Note that now we can recover the true value of the invisible energy within a few % for all models and primaries. Note also how we improve the estimation of E_{inv} for QGSJetII-03, even though the primary mass composition used to parametrize $A(\Delta X)$ is different from that of the simulated events used to test the analysis method. In the next section, we see how the parametrization of Eq. (14) is used to estimate the invisible energy of the Auger data.

C. E_{inv} from Auger data and its parametrization as a function of the calorimetric energy

The analysis methods described in Secs. IV A and IV B allow us to obtain an event-by-event estimation of E_{inv} for the data collected by the Pierre Auger Observatory. We recall that the vertical events are those with zenith angles $\theta < 60^\circ$, while inclined events have $60^\circ < \theta < 80^\circ$. For both data sets, the analysis is limited to those events sufficiently energetic to ensure a full trigger efficiency. In fact, at lower energies the trigger is biased towards events with a higher number of muons and thus higher invisible energy, and consequently larger systematic uncertainties. The energy thresholds for the full trigger efficiency are 4×10^{18} eV for the inclined [16] and 3×10^{18} eV for the vertical events [42].

FIG. 5. Average value of the relative difference between the true value of E_{inv} and the value of E_{inv} reconstructed from $S(1000)$ and X_{max} using Eq. (11) (left) and after applying the correction due to the difference among the simulations in the predictions of the number of muons and in the attenuation function, using Eq. (14) (right). The simulations refer to vertical showers.

In order to obtain an invisible energy estimation that can be used for all events detected by the FD, including the ones with energies below the full SD trigger efficiency, the event-by-event estimation of E_{inv} is parametrized as a function of the calorimetric energy above the full trigger efficiency, with the function being extrapolated to lower energies.

The parametrization is obtained by analyzing a sample of hybrid showers selected with the same selection criteria used for the energy calibration of the SD energy estimators [19].

SD events are selected by requiring that the WCD with the highest signal is enclosed within a hexagon of six active stations. This is the basic cut used to calculate the aperture of the SD [42], and it rejects events that can be affected by large uncertainties because they fall near the edge of the array or in regions where a station is temporarily not fully operational.

FD events are selected in order to guarantee a precise reconstruction of the longitudinal profile. Good atmospheric conditions are ensured by requiring that the vertical aerosol optical depth is measured within 1 hour of the time of the event and its value at 3 km above ground level is less than 0.1. Moreover, information from the Auger infrared cloud cameras, laser facilities, LIDAR stations, and the Geostationary Operational Environmental Satellites (GOES) database are used to discard events detected by telescopes that have clouds in their fields of view [20]. Next, a set of quality selection cuts is applied to obtain a precise reconstruction of the energy deposit dE/dX . The total track length (that is, the entire range of depths along which dE/dX is measured) must be at least 200 g/cm^2 . Events are rejected if there is a gap in the energy deposit profile larger than 20% of the total track length. The error on the reconstructed calorimetric energy must be less than 20%, and the residual in the Gaisser-Hillas fit, $(\chi^2 - n_{\text{dof}})/\sqrt{2n_{\text{dof}}}$, must be less than 3. Finally, a set of cuts related to the field of view of the telescopes is applied. The field of view is defined by lower (X_l) and upper (X_u) depth boundaries and must be large enough to have equal sensitivity to an appropriately large range of values of the depth of shower maximum X_{max} . The cut ensures that the maximum accepted uncertainty in X_{max} is 40 g/cm^2 (150 g/cm^2) and that the minimum viewing angle of light in the telescope is 20° (25°) for the vertical (inclined) showers. Furthermore, the values of X_l and X_u need to be within certain limits in order to enclose the bulk of the X_{max} distribution. The overall purpose of field-of-view cuts is to select primaries with different masses with the same probability [20].

A last cut is applied to the FD energies and ensures that the SD trigger efficiency is close to 100%. Since at this stage of the analysis the invisible energy is not known, the cut is applied to the calorimetric energies, requiring that they are larger than $3.5 \times 10^{18} \text{ eV}$ for the inclined showers and $2.5 \times 10^{18} \text{ eV}$ for vertical events. These correspond to

the energy thresholds for full trigger efficiency assuming that the invisible energy is about 15% of the total shower energy [43].

The analysis is performed over the hybrid events collected from 1 January 2004 to 31 December 2015, and the selected data set consists of 310 inclined and 2827 vertical events.

As seen in Sec. IV B, an unbiased estimate of E_{inv} in vertical showers requires the two corrections shown in Eq. (14), one related to the attenuation $[\gamma_0(\Delta X)]$ and the other to the muon number (β_0). The ratio $\tilde{\gamma}_0(\Delta X)/\gamma_0(\Delta X)$ is obtained by doing a fit to the hybrid data [ratio of $S(1000)^\gamma$ to the FD energy in bins of ΔX] to extract $\gamma_0(\Delta X)$. As the statistics are too limited below $\Delta X = 250 \text{ g/cm}^2$ and above $\Delta X = 1000 \text{ g/cm}^2$ for sufficiently small bins of ΔX , and considering that the uncertainty on the FD energy becomes larger when the maximum of the energy deposit is close to ground level, the applicability of the method is presently limited to this range. Thus, a further cut on ΔX is applied to the vertical events, requiring it to be in the above range and, from among the 2827 events, 2389 are selected. The correction factor β_0/β_0 is estimated from the ratio of the average muon number measured in inclined events and the muon number predicted by the model used to calculate the function $A(\Delta X)$ (QGSJetII-03 [29] for a mixed composition of 50% protons and 50% iron). Further details on the calculation of the two corrections are reported in Appendix A. The two corrections are rather large, but they partially compensate for each other. The average value of $(\tilde{\gamma}_0/\gamma_0)^\beta$ ($\beta = 0.925$) is about 0.73 and almost the same at all energies. It essentially reflects the mismatch between the energy estimation provided by the simulations and that given by the fluorescence measurements. The correction β_0/β_0 is about 1.55 and slightly increases with energy. Despite their large values, the overall correction is only about 1.15.

The correlation between E_{inv} and E_{cal} is well approximated by a power-law relationship

$$E_{\text{inv}} = a \left(\frac{E_{\text{cal}}}{10^{18} \text{ eV}} \right)^b \quad (15)$$

where the parameters a and b are fitted to the data using a maximum-likelihood method [43] that allows us to correctly take into account the cut on energy for the full trigger efficiency, avoiding the bias that would be introduced by a standard least-squares fit. The calculation of the probability density function includes the event-by-event uncertainties on E_{cal} and E_{inv} . A detailed description of the uncertainty on E_{cal} is reported in [19]. The uncertainties on E_{inv} for the inclined events are obtained by propagating the event-by-event errors on R_μ as given by the fit of the muon number density [16]. For the vertical events, the uncertainties arising from $S(1000)$ are calculated as reported in [43], and these dominate over the contribution given by the errors on X_{max} . The uncertainties on the invisible energy

TABLE II. Values of the parameters of Eq. (15) fitted to the data. The errors are statistical, and ρ is the correlation coefficient.

Data sample	$a[10^{18} \text{ eV}]$	b	ρ
Inclined	0.179 ± 0.006	0.947 ± 0.017	-0.96
Vertical	0.160 ± 0.002	0.952 ± 0.005	-0.94

include a contribution from the shower-to-shower fluctuations with a value inferred from the data, requiring that the reduced χ^2 is approximately equal to 1. This uncertainty amounts to 14% and 11% for the inclined and vertical data sets, respectively.

The results of the fit are shown in Table II, and the data and the fitted functional forms are shown in Fig. 6. The data are presented in terms of the ratio E_{inv}/E_0 [with $E_0 = E_{\text{cal}} + a(E_{\text{cal}}/\text{EeV})^b$] to be consistent with the previous figures.

Having determined the parameters a and b , it is possible to estimate the resolution in E_{inv} from the data. In Fig. 7 we show the distribution of the residuals between E_{inv} and the invisible energy calculated from E_{cal} . The width of these distributions is determined by the combined effect of the resolutions on E_{inv} and E_{cal} , and then, knowing that the resolution on FD energies is 7.6% [19], it is possible to estimate the resolution on E_{inv} . The fit done using a Gaussian ratio probability density function yields $(16.8 \pm 0.8)\%$ and $(14.4 \pm 0.3)\%$ for inclined and vertical events, respectively, in good agreement with the expected uncertainties.

In the end, in Fig. 7 we show that the residual distributions are in good agreement with the expected ones (shown with solid lines) calculated from the probability model used to fit the a and b parameters, further demonstrating the correctness of the estimation of the uncertainties.

D. Systematic uncertainties

As seen in Sec. IV A, the analysis method to estimate the invisible energy in inclined events allows us to recover the true value of E_{inv} within 10% for several hadronic interaction models and primary masses (see Fig. 4). The deviations arise from the slight model dependence of the parameters used to get E_{inv} from R_μ and from the uncertainty in the R_μ reconstruction. An additional uncertainty related to the influence of the inclined events close to 60° , for which the electromagnetic correction is not negligible [16], is evaluated using data. Excluding events with zenith angles below 65° , the fitted parametrization of E_{inv} as a function of E_{cal} changes by less than 2%. Finally, the statistical errors on the a and b parameters cause an uncertainty in E_{inv} below 5%. The first two uncertainties are both related to the assumption on the primary mass composition and are expected to be partially anticorrelated [for heavier primaries, we have larger values of C in Eq. (7) and a smaller electromagnetic correction that causes a decrease of C]. Thus, a conservative estimate of a total uncertainty of about 12% is obtained by neglecting such correlation and adding all contributions in quadrature.

Concerning the vertical events, we have seen in Sec. IV B that the analysis method allows us to recover the correct E_{inv} well within 5%, which we conservatively consider as a systematic uncertainty. Other contributions to the uncertainty arise from the statistical error on the a and b parameters ($<2\%$), from the systematic uncertainty in the X_{max} scale (1%), and from the uncertainty in the β_0 correction (the statistical error on the parametrization of N_{19} as a function of energy and systematics related to the electromagnetic correction, with an overall contribution of less than 4%). Another uncertainty comes from a possible correction for the exponent B of the power-law relationship between E_{inv} and $S(1000)$ [see Eq. (11)]. Changing B by

FIG. 6. Invisible energy fraction from the hybrid data as a function of the calorimetric energy. The estimations obtained with inclined and vertical events are shown in the left and right figures, respectively. Each point represents an individual event, and the error bars are calculated by propagating the uncertainties in E_{cal} and R_μ . The results of a fit of a power-law functional form are shown with red lines.

FIG. 7. Distribution of the residuals between the E_{inv} estimates and the values obtained from E_{cal} using the fitted power-law relationship, for inclined (left) and vertical (right) events. The expected distributions for the residuals calculated from the probability model used for the fit are shown with solid lines.

2%, we estimate an uncertainty in E_{inv} that increases with energy from 5% to 11%. A total uncertainty of 11%–16% (larger at higher energies) is obtained by assuming that the errors on B and the 5% addressed in Sec. IV B are fully correlated (both depend on the model and primary mass used to estimate the parameters) and noting that the other uncertainties are expected to be largely uncorrelated.

V. DISCUSSION OF THE RESULTS AND EXTRAPOLATION TO LOW ENERGIES

For a quantitative comparison of the two data-driven estimations of E_{inv} presented in the previous section, one has to take into account that E_{inv} has a zenith angle dependence, being larger for showers at larger zenith angles. The zenith angle dependence of E_{inv} has been studied by simulating proton and iron showers at $10^{18.5}$ eV using the AIRES [34] code with the QGSJetII-03 [29] hadronic interaction model and parametrized with an analytical function that is reported in Appendix B. We find that the average values of E_{inv} for the two data sets differ by 5%: $E_{\text{inv}}(41^\circ)/E_{\text{inv}}(66^\circ) \simeq 0.95$, where 66° and 41° are the average zenith angles of the inclined and vertical data, respectively. Then, for a correct comparison, one of the two estimates has been corrected by this ratio. Since the majority of the events have zenith angles below 60° , in the following we correct the E_{inv} parametrization obtained from the inclined data set, multiplying the corresponding parametrization as a function of E_{cal} by 0.95.

The two data-driven E_{inv} estimations are compared in Fig. 8. They are in excellent agreement, well within the systematic uncertainties that are shown with shaded bands. It is worth noting that the two estimates are partially correlated since they both use the measurement of the muon number. However, they are affected by different systematics, and in particular, those arising from the model

dependence of the parameters used to get E_{inv} from the shower observables are not expected to be significantly correlated. In fact, in inclined events, the largest model dependence arises from ϵ_c^π , while in vertical events, the uncertainty in this parameter only marginally affects the invisible energy since $E_{\text{inv}} \propto (\epsilon_c^\pi)^{1-\beta}$ with $\beta \approx 0.9$.

In Fig. 8, we also show the theoretical predictions for the different hadronic interaction models and primary masses addressed in Sec. III. Note that, in comparison to the predictions of the pre-LHC models (left panel), our estimations are in better agreement with the ones of the post-LHC models (right panel). However, they still have large values, even larger than the predictions for iron primaries, in contradiction with the mean mass composition obtained using the X_{max} measurement [20]. This is a consequence of the muon number deficit in models [37], given that the models fail to describe the properties of shower development related to muons and therefore to E_{inv} .

The estimations of E_{inv} have been obtained for energies above the threshold for the full trigger efficiency of the SD. They can be extrapolated to lower energies by taking into account the change in the elongation rate (i.e., how the mean mass composition evolves with energy) measured by Auger at $E_{\text{cal}}^A \simeq 2 \times 10^{18}$ eV [20,44]. The function is obtained by extrapolating the parametrization obtained from data down to E_{cal}^A and, below this energy, using a model inspired function that matches the parametrization at E_{cal}^A .

For the latter, we use the function of Eq. (5) in which the mean composition as a function of energy is taken from the Auger FD measurements [44] together with a value of $\beta = 0.9$ that reproduces the simulations at lower energies. Then the extrapolated function is approximated by a simple power-law function of E_{cal} with the exponent $b_{\text{extr}} = 0.846$. The value of b_{extr} reflects how the mass composition evolves with energy, and the particular value chosen for β .

The extrapolation of E_{inv} obtained from the inclined events is shown with the black dashed line in Fig. 8.

FIG. 8. Invisible energy obtained for inclined and vertical events compared with the predictions given by Monte Carlo simulations. The estimate for inclined events is extrapolated to low energies, and the systematic uncertainties of both estimations are shown with the shaded bands. The simulations are performed for proton (solid lines) and iron (dashed lines) primaries and different hadronic interaction models. Left panel: EPOS 1.99 [28], QGSJet01 [30], and QGSJetII-03 [29]. Right panel: EPOS LHC [25], QGSJetII-04 [26], and Sibyll2.3c [27].

A smooth transition between the power law valid below E_{cal}^A and the one valid at higher energies (shown with the solid black line) is obtained with a hyperbolic tangent function. Further details on the functional shape that parametrizes E_{inv} are reported in Appendix B.

The uncertainty in the extrapolation (shown with the shaded band) is obtained by adding in quadrature the 12% error on the estimate at higher energies and a contribution (15% at 10^{17} eV that progressively reduces to 0 as we approach E_{cal}^A) obtained by changing β over a wide range (0.87–0.93).

From Fig. 8, one can see how the rate with which E_{inv} evolves with energy is different above and below E_{cal}^A . This is a consequence of the change in the elongation rate. Moreover, the constraint to match our estimation of E_{inv} at E_{cal}^A helps us obtain a more realistic estimation of the extrapolation. However, it is worth noting that this is still an extrapolation that uses measurements of the number of muons at high energy that show an excess with respect to the predictions of the hadronic interaction models. The muon number excess could be different at low energies, and this could introduce additional biases in E_{inv} . A more accurate estimation of E_{inv} will be obtained in the near future using the data collected by the AMIGA muon detectors [45] installed at Auger and using the 750-m-spacing subarray of WCDs [8].

VI. CONCLUSIONS

We have presented a data-driven estimation of the invisible energy of cosmic ray showers detected by the Pierre Auger Observatory. We have developed two analysis methods for the SD events inclined at zenith angles $60^\circ < \theta < 80^\circ$ and for hybrid showers with $\theta < 60^\circ$. The invisible energy has been parametrized as a function of

the calorimetric energy and extrapolated to energies below the full trigger efficiency of the SD.

The two estimations agree at a level well within the systematic uncertainties that are estimated to be of the order of 10%–15%, and they give values of E_{inv} considerably higher than the predictions given by Monte Carlo simulations. This is a consequence of the muon number deficit in models [37], a deficit due to the failure of the hadronic interaction models to describe the properties of shower development related to muons. Moreover, the estimations are consistent with the evolution of the mass composition with energy as measured by Auger [20,44]. This is due to the sensitivity of the muon number to the primary mass and, at lower energy, due to the use of the mean mass composition to find the functional form that describes E_{inv} as a function of E_{cal} .

While the two estimations are affected by comparable systematic uncertainties, the one obtained using the inclined events is intrinsically better. In fact, for these showers, we measure the total number of muons arriving at ground level, which makes the analysis of E_{inv} rather straightforward, more direct, and simpler than the analysis used for vertical events.

A preliminary data-driven estimation of E_{inv} has already been in use by Auger for several years [13,14]. Before 2013, we used a parametrization fully based on simulations assuming a mixed composition of proton and iron primaries [6], which is shown in Fig. 9 and compared with the E_{inv} estimate obtained in this paper from the analysis of inclined events and extrapolated to low energies. In the same figure, we also show the parametrizations obtained in [6] for proton and iron primaries and the parameterization in use by the Telescope Array Collaboration, which assumes a proton composition [46]. The systematic uncertainty in our estimation is depicted with a shaded band. From the figure one can evaluate the impact of the data-driven estimation of E_{inv} on the energy scale of Auger. Using the two

FIG. 9. Auger data-driven estimation of the invisible energy compared with the parametrizations for protons, iron, and mixed composition reported in [6], and the one used by the Telescope Array [46].

simulations, we could introduce a bias in the energy scale of -4% and -6% , which is significant considering that the systematic uncertainty in the energy scale introduced by the E_{inv} estimate presented in this paper is about 1.5% .

A precise determination of the energy scale is particularly important for the measurement of the energy spectrum of the cosmic rays. The spectrum falls off with energy approximately as a power-law function ($J \propto E^{-\gamma}$) with a power index γ of about 3, and, at the highest energies, it manifests a flattening at about 5×10^{18} eV (a feature known as an ankle) and an abrupt suppression above 10^{19} eV [43]. Note that J is measured by counting the number of events in bins of energy, and it is very sensitive to the energy scale because the systematic uncertainties affecting the shower energy ($\Delta E/E$) are amplified by the spectral index through the factor $(1 - \Delta E/E)^{-\gamma+1}$. Then one can infer the impact of the data-driven estimation of E_{inv} in the spectrum. Using the two simulations of Fig. 9 we could underestimate by about -4% and -6% the energies at which we observe the spectral features and introduce a negative bias in the flux J even larger than 10% .

The invisible energy parametrization as a function of E_{cal} obtained using the Auger data can also be used in other experiments employing the fluorescence technique. Note that in this case, the uncertainty in E_{inv} remains the one determined in this paper only if the relative calibration factor between the energy scales of the second experiment and Auger is known and taken into account in the calculation of E_{inv} . Otherwise, a correct estimation of the uncertainty in E_{inv} needs to take into account the uncertainties in the energy scales of both experiments.

ACKNOWLEDGMENTS

The successful installation, commissioning, and operation of the Pierre Auger Observatory would not have been

possible without the strong commitment and effort from the technical and administrative staff in Malargüe. APPENDIX A: PARAMETERS RELEVANT FOR THE E_{inv} ESTIMATION IN VERTICAL SHOWERS

Both $A(\Delta X)$ [$=E_{\text{inv}}/S(1000)^B$, see Eq. (11)] and $\gamma(\Delta X)$ [$=E_o/S(1000)^\gamma$, see Eq. (9)] are parametrized in units of GeV with the function $10^{f(\Delta X)}$, where the exponent is a fourth-degree polynomial in $\Delta X = (875/\cos\theta - X_{\text{max}})$ [g/cm²],

$$f(\Delta X) = p_0 + p_1 \frac{\Delta X}{1000} + p_2 \left(\frac{\Delta X}{1000} \right)^2 + p_3 \left(\frac{\Delta X}{1000} \right)^3 \quad (\text{A1})$$

and where the values of the parameters are shown in Table III.

TABLE III. Values of the parameters that define the functions $A(\Delta X)$ and $\gamma_0(\Delta X)$ [see Eq. (A1)].

		p_0	p_1	p_2	p_3
$A(\Delta X)$	QGSJetII-03 [29]				
	–50% p 50% Fe	7.396	–0.696	2.310	–1.224
$\gamma_0(\Delta X)$	QGSJetII-03 [29]—p	8.363	–0.651	2.486	–1.353
	QGSJetII-03 [29]—Fe	8.215	–0.293	1.829	–1.034
	Hybrid data	8.306	–0.984	2.644	–1.454

The function $\gamma_0(\Delta X)$ for a mixed composition of 50% protons and 50% iron is calculated by taking the average of the functions γ_0 for proton and iron primaries. All the parametrizations, together with the average values of $S(1000)^\gamma/E$ in bins of ΔX obtained with the hybrid data, are shown in the left panel of Fig. 10. Note that $\gamma_0(\Delta X)$ for data is calculated by assuming $\gamma = 1.0594$, the value that reproduces the QGSJetII-03 simulations (see Sec. IV B).

The average values of the corrections $(\tilde{\gamma}_0/\gamma_0)^\beta$ ($\beta = 0.925$) and $\tilde{\beta}_0/\beta_0$ calculated in bins of shower energy for the hybrid data sample selected to evaluate E_{inv} are shown in the right panel of Fig. 10. Note that $\tilde{\gamma}_0$ and γ_0 refer to data and QGSJetII-03 simulations for the mixed composition, respectively. Here, $\tilde{\beta}_0/\beta_0$ represents the muon number excess obtained in inclined events with respect to the muon number predicted by QGSJetII-03 [29] for a mixed composition of 50% protons and 50% iron. It is estimated from the parametrization of N_{19} as a function of energy [43] and the parametrizations of R_μ for the QGSJetII-03 simulations for proton and iron primaries [37]:

$$\frac{\tilde{\beta}_0}{\beta_0} = N_{19}(E) \frac{R_\mu^p(10^{19} \text{ eV})}{(R_\mu^p(E) + R_\mu^{\text{Fe}}(E))/2}. \quad (\text{A2})$$

FIG. 10. Left: The inverse of $\gamma_0(\Delta X)$ as predicted by the QGSJetII-03 [29] simulations and as parametrized using the hybrid data. Right: Mean values of the correction factors needed to estimate E_{inv} from data calculated in bins of shower energy.

APPENDIX B: E_{inv} PARAMETRIZATION AS A FUNCTION OF E_{cal} INCLUDING THE EXTRAPOLATION TO LOW ENERGIES AND THE ZENITH ANGLE DEPENDENCE

The function that parametrizes E_{inv} as a function of E_{cal} and extrapolates to 10^{17} eV is

$$E_{\text{inv}} = f(\theta)E_{\text{inv}}^l + f(\theta)\frac{1}{2}\left[1 + \tanh\left(K\log_{10}\frac{E_{\text{cal}}}{E_{\text{cal}}^A}\right)\right](E_{\text{inv}}^h - E_{\text{inv}}^l),$$

where E_{inv}^h is the parametrization obtained from the analysis of the inclined events (see Sec. IV C) and E_{inv}^l describes the extrapolation down to low energies:

$$E_{\text{inv}}^l = a\left(\frac{E_{\text{cal}}^A}{10^{18} \text{ eV}}\right)^b \left(\frac{E_{\text{cal}}}{E_{\text{cal}}^A}\right)^{b_{\text{extr}}}$$

$$E_{\text{inv}}^h = a\left(\frac{E_{\text{cal}}}{10^{18} \text{ eV}}\right)^b.$$

The hyperbolic tangent ensures a smooth transition between the functions E_{inv}^l and E_{inv}^h that describe the invisible energy below and above E_{cal}^A , respectively, E_{cal}^A being the energy at which Auger measures a break in the elongation rate [20].

TABLE IV. Values of the parameters needed to calculate the invisible energy parametrization.

$a[10^{18} \text{ eV}]$	b	$E_{\text{cal}}^A[10^{18} \text{ eV}]$	K	b_{extr}	f_1	f_2	f_3
0.179	0.947	1.95	4	0.846	-0.265	0.489	-0.441

The function $f(\theta)$ describes the zenith angle dependence of E_{inv} . It is parametrized with a third-degree polynomial that is normalized to 1 at the average zenith angle of the inclined hybrid events (66°):

$$f(\theta) = 1 + f_1(\cos\theta - \cos 66^\circ) + f_2(\cos\theta - \cos 66^\circ)^2 + f_3(\cos\theta - \cos 66^\circ)^3.$$

The values of the parameters defining the invisible energy parametrization are shown in Table IV.

The systematic uncertainty on E_{inv} is parametrized with the following function,

$$\frac{\Delta E_{\text{inv}}}{E_{\text{inv}}} = \sqrt{0.12^2 + \left[0.15\left(1 - \frac{\log_{10}(E_{\text{cal}}/10^{17})}{\log_{10}(E_{\text{cal}}^A/10^{17})}\right)\right]^2} \quad (\text{B1})$$

for $10^{17} \text{ eV} < E_{\text{cal}} < E_{\text{cal}}^A$, and is fixed to $\frac{\Delta E_{\text{inv}}}{E_{\text{inv}}} = 0.12$ for $E_{\text{cal}} > E_{\text{cal}}^A$.
