Vicentini et al (J. Inorg. Nucl. Chem., 37, 2021, 1975) synthesized a series of complexes  $\text{Ln}(\text{PF}_6)_3 \cdot 4\text{TDTD} \cdot 4\text{H}_2\text{O}$  ( $\text{Ln} = \text{La-Lu, Y}$ ; TDTD = 1,4 - dithiane - 1,4 - dioxide) as very fine powders. Recrystallized single crystals are always complexly twinned and show the same D-S powder pattern as the original powders. Precession, Weissenberg and rotation methods were used to determine the crystallographic characteristics of the compounds with  $\text{Ln} = \text{La, Ce, Yb}$ . The La and Ce compounds are monoclinic with  $\beta$  close to  $90^\circ$ , and  $P2, Pm, P2/m$  as possible space groups (diffraction symbol is  $2/mP \dots$ ). The Yb compound shows orthorhombic symmetry, space group  $\text{Pnca}$  ( $\text{Pbcn}$  is the standard orientation). Doubling of two axes increases the unit cell content from 1 in the monoclinic to 4 in the orthorhombic crystals. D-S powder films were made of all the recrystallized material ( $\text{Cr K}\alpha$ ,  $\text{Si}$  as internal standard) and a few lines computer-indexed. Cell constants were calculated using conventional least-squares computer methods. All complexes with  $\text{Ln} = \text{Y, La to Tm}$ , have comparable powder patterns and are thus monoclinic, while the Lu pattern is identical to that of the orthorhombic Yb. Cell parameters, change from  $a = 9.05(1)$ ,  $b = 9.12(2)$ ,  $c = 12.44(1)$  Å,  $V = 1026(2)$  Å<sup>3</sup> (Y compound) to  $a = 8.93(1)$ ,  $b = 9.31(2)$ ,  $c = 12.41(2)$  Å,  $V = 1031(2)$  Å<sup>3</sup> (Tm compound) while  $\beta$  changes from  $92^\circ 06'(6)$  to  $91^\circ 51'(10)$ ; corresponding data for the Yb compound are  $17.19(4)$ ,  $17.75(3)$ ,  $13.37(2)$  Å,  $V = 1020(3)$  Å<sup>3</sup> (V per molecule). There is, within the low resolution of the cell parameters, an irregular tendency for the cell parameters to decrease, probably controlled by a small overall lanthanide contraction effect (Siekierski, J. Inorg. Nucl. Chem., 33, 377, (1971)).
