31 **Abstract**

32 This study evaluated the impact of the direct *in situ* generation of hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>)  
33 in urine through the application of gas diffusion electrode based on Printex L6 carbon. The  
34 oxidative potential of H<sub>2</sub>O<sub>2</sub> was explored to promote the degradation of urea, creatinine, and  
35 uric acid. Different current densities (25, 50, 75, and 100 mAcm<sup>-2</sup>) were tested for H<sub>2</sub>O<sub>2</sub>  
36 electro-generation in Na<sub>2</sub>SO<sub>4</sub> under ionic strength and pH conditions similar to those of  
37 synthetic urine. The current density of 50 mAcm<sup>-2</sup> was found to provide the best balance of  
38 H<sub>2</sub>O<sub>2</sub> production, energy efficiency, and energy consumption; under these conditions, the  
39 concentration of H<sub>2</sub>O<sub>2</sub> electrogenerated was compared with that accumulated in the urine  
40 matrix itself, both in the presence and absence of organic compounds. The results showed that  
41 the compositional complexity of urine extends beyond organic compounds, and the significant  
42 difference in H<sub>2</sub>O<sub>2</sub> generation between Na<sub>2</sub>SO<sub>4</sub> and the synthetic inorganic urine matrix can  
43 be attributed to the presence of dissociated ions or species generated during the electrolytic  
44 process, with active chlorine species playing a notable role. The direct electrogeneration of  
45 H<sub>2</sub>O<sub>2</sub> in urine resulted in the removal of 43.4% urea, 77.2% creatinine, and 100% uric acid,  
46 with partial mineralization of 31% and a lower energy consumption of 6.21 kWh (g TOC)<sup>-1</sup>  
47 compared with the process that did not involve the *in situ* generation of H<sub>2</sub>O<sub>2</sub>. The study  
48 highlights a promising strategy for sustainable electro-sanitation practices, offering valuable  
49 contributions toward advancing the achievement of the United Nations' Sustainable  
50 Development Goals (SDG), particularly in regions with limited access to basic sanitation. By  
51 utilizing the urine matrix for *in situ* hydrogen peroxide generation, this approach fosters  
52 decentralized solutions for wastewater treatment.

53

54 **Keywords:** Gas diffusion electrodes, *in situ* H<sub>2</sub>O<sub>2</sub> generation, synthetic urine, electro-  
55 sanitation, sustainability.

## 56 1. Introduction

57 The Sustainable Development Goals (SDGs), launched in 2015 by the United Nations  
58 (UN), represent a global commitment to addressing the most pressing social, economic, and  
59 environmental challenges of our planet by 2030 [1]. Among these goals, the SDG 6, which  
60 aims to ensure universal access to clean water and adequate sanitation, stands out as one of  
61 the most crucial and ambitious goals that are geared toward promoting and safeguarding  
62 global public health and well-being. Despite the initial optimism, current projections suggest  
63 that we are unlikely to achieve the SDG 6 by 2030, with some estimates extending the  
64 timeline for meeting the guidelines and accomplishing the target to 2050 [2]. This concern  
65 regarding the inability to accomplish the SDG 6 by the set deadline was reinforced by the  
66 2023 UN World Water Report, which showed that approximately 46% of the global  
67 population still lacks access to basic sanitation, while 26% lives without access to safe  
68 drinking water [3].

69 In this context, for the pursuit and accomplishment of the SDGs, scientific research is  
70 found to play a key transformative role which involves both collective and individual efforts  
71 [4]; specifically, scientific research plays a crucial role when it comes to treating the  
72 increasingly complex nature of urban wastewater, including highly challenging effluents such  
73 as urine. The complex nature of urine can be primarily linked to its compositional variability,  
74 which depends on factors such as age, gender, geographic location, environmental conditions,  
75 and diet [5]. Urine primarily contains inorganic compounds such as chloride, sulfate, and  
76 phosphate, as well as a high organic load which is derived from its urea, creatinine, and uric  
77 acid contents [6,7]. The complex nature of urine makes it difficult to be treated effectively,  
78 and this underscores the need for the development of highly efficient technologies that are  
79 capable of treating such matrices in an adequate fashion. Centralized wastewater treatment  
80 systems have proven to be ineffective when applied for the treatment of urine due to the  
81 logistics involved in transporting large volumes of urine [8,9]. For example, an adult produces  
82 an average of 1.4 liters of urine per day [5], and this volume is further diluted by water during  
83 flushing, where roughly 10 times more water is used for its disposal [10].

84 This reality points to the urgent need for devising innovative, efficient, and  
85 decentralized sanitation solutions for wastewater treatment, especially in remote areas with  
86 limited infrastructure [11,12]. Among these approaches, a comprehensive state-of-the-art  
87 study published in 2021 highlighted recent efforts to develop urine treatment technologies.  
88 This study revealed that while biological processes are effective for urine stabilization, they  
89 are not suitable for toilet applications [13]. This limitation can be overcome by advanced  
90 oxidation processes (AOP), such as electrochemical oxidation (EO), which has gained  
91 prominence among researchers due to the efficiency and flexibility of these processes when  
92 applied for the removal of organic compounds from complex matrices [14–16]. The efficiency  
93 of EO depends, among other factors, on the electrogeneration of strong oxidants, including  
94 hydroxyl radicals, active chlorine species, and hydrogen peroxide ( $H_2O_2$ ) [17].  $H_2O_2$  is a  
95 versatile oxidant which is widely employed in environmental applications; the *in situ*  
96 generation of  $H_2O_2$  offers significant advantages, as it helps eliminate the need for  
97 transporting and storing large volumes of reagents [18,19].  $H_2O_2$  can be generated and  
98 accumulated in desirable concentrations during continuous electrolysis, primarily through the  
99 two-electron oxygen reduction reaction (ORR), as shown in Eq. 1 [19,20].

102

103 The synthesis of  $H_2O_2$  is not an easy task [21], but the underlying difficulties  
104 encountered in  $H_2O_2$  generation can be overcome through the use of gas diffusion electrodes  
105 (GDE). The use of GDEs allows one to perform electrolysis under ambient pressure and  
106 temperature while ensuring that the oxidant is in direct contact with the pollutants in the  
107 solution being treated (Carneiro et al., 2016). The efficiency of GDEs for ORR depends,  
108 among other factors, on the catalytic material used. Carbon-based materials, such as Printex  
109 L6, have demonstrated high efficacy when applied in the construction of catalytic materials;  
110 these carbon-based materials have been found to facilitate the occurrence of ORR selectively  
111 due to their large surface area and the presence of functional groups in them which help  
112 enhance their catalytic activity [23].

113 Given these well-established advantages of EO, it is clear that the process meets many  
114 of the standard prerequisites for application in decentralized wastewater treatment systems.  
115 Remarkably, despite the recent progress, significant gaps remain when it comes to devising  
116 suitable technologies for the treatment of real and complex matrices such as synthetic urine.  
117 Thus, this study aims to investigate the application of electrochemical oxidation with *in situ*  
118  $H_2O_2$  generation and Printex L6 carbon-based gas diffusion electrode (GDE/PL6C) for the  
119 efficient treatment of synthetic urine. The primary focus of the study lies in using the  
120 proposed treatment mechanism for the degradation of key organic compounds, such as urea,  
121 creatinine, and uric acid, whose degradation poses significant challenges to sanitary effluent  
122 treatment systems. This study deepens our understanding of advanced treatment processes for  
123 complex matrices, providing crucial insights into the development of efficient and affordable  
124 technologies for decentralized electro-sanitation practices. In this sense, the present study  
125 directly contributes to the development of wastewater treatment solutions which can help  
126 accelerate the progress toward the accomplishment of safe and sustainable sanitation goals,  
127 including, in particular, the SDG 6.

128

## 129 2. Experimental

### 130 2.1. Chemicals and synthetic urine formulation

131 The synthetic urine matrix was formulated based on a composition described in the  
132 literature, as shown in Table 1. All the reagents – acquired from Sigma-Aldrich, used in the  
133 experiments were of analytical grade. The solutions were prepared using ultrapure water  
134 obtained from a Merck Milli-Q system, with resistivity of 18.2 M $\Omega$  cm.

135

136 **Table 1:** Composition of the synthetic urine matrix adapted from Arve and Popat (2021) and Felisardo  
137 et al. (2024b) as representative of domestic urine.

---

Species

Concentration (molL<sup>-1</sup>)

Chemical name	Chemical formula	MW (gmol <sup>-1</sup> )	
Urea	CH <sub>4</sub> N <sub>2</sub> O	60.06	0.0550
Creatinine	C <sub>4</sub> H <sub>7</sub> N <sub>3</sub> O	113.12	0.0015
Uric acid	C <sub>5</sub> H <sub>4</sub> N <sub>4</sub> O <sub>3</sub>	168.11	0.0003
Sodium chloride	NaCl	58.44	0.1200
Sodium sulfate	Na <sub>2</sub> SO <sub>4</sub>	142.00	0.0200
Potassium chloride	KCl	74.55	0.0600
Monosodium phosphate	NaH <sub>2</sub> PO <sub>4</sub>	119.98	0.0200
<b>Total organic carbon (TOC)</b>			750 mg L <sup>-1</sup>
<b>pH</b>			5.26
<b>Ionic strength</b>			0.3 mol L <sup>-1</sup>
<b>Conductivity</b>			18.29 mS cm <sup>-2</sup>

138

139 The ionic strength of the solutions was calculated using the Lewis and Randall  
 140 equation, as expressed in Eq. 2 below [25].

141

$$142 \quad I = \frac{1}{2} \sum C_i Z_i^2 \quad (\text{Eq. 2})$$

143

144 Where  $I$  is the ionic strength in mol L<sup>-1</sup>,  $C_i$  is the concentration of ion  $i$  in mol L<sup>-1</sup>, and  $Z_i$  is the  
 145 charge of ion  $i$  present in the solution.

146

## 147 2.2. Preparation of GDE with Printex L6 carbon and H<sub>2</sub>O<sub>2</sub> electrogeneration

148

149 The gas diffusion electrode was prepared based on the standard method developed by  
150 our research group [23,26]. Specifically, a catalytic mass of 1.6 g of PL6C, previously dried  
151 in an oven for 24 h at 120°C, was mixed with 25 mL of ultrapure water until a completely  
152 homogeneous mixture was obtained. Poly(tetrafluoroethylene) (PTFE) (Daflon Co.) was then  
153 added to the mixture in a proportion of 20% of the total mass. The mixture was stirred for 45  
154 min at 500 rpm. After that, the resulting catalytic mass was evenly dispersed on carbon cloth  
155 attached to a metal mold, and then kept in an oven for 15 min at 120°C in order to obtain a  
156 dispersed mass with a moist appearance. Subsequently, the cloth with the PL6C mass was  
157 removed from the metal mold, and a second cloth of the same dimensions was placed on top  
158 of it. The material prepared was then pressed (SOLAB SL-11) at 0.5 tons, at the temperature  
159 of 290°C for 45 min.

160 Figure 1 presents the operational system used for the conduct of the experiments. The  
161 system consisted of a single-compartment cylindrical glass electrochemical cell, equipped  
162 with Ag/AgCl reference electrode - from ANALYSER 3A11, a dimensionally stable anode  
163 (DSA<sup>®</sup>) of Ti/RuO<sub>2</sub>-TiO<sub>2</sub> used as the counter electrode, and the GDE/PL6C used as the  
164 working electrode. The GDE/PL6C and DSA<sup>®</sup> had a geometric area of 20 cm<sup>2</sup> each. The  
165 GDE/PL6C was positioned at the base of the electrochemical cell, where O<sub>2</sub> was injected  
166 directly at a fixed flow rate of 0.05 Lmin<sup>-1</sup>. The oxygen flow rate was chosen based on  
167 previous studies of our research groups, which indicated that above this value no further  
168 improvement in H<sub>2</sub>O<sub>2</sub> production is achieved [27]. The temperature of the electrochemical  
169 cell was maintained constant at 20°C with the aid of a thermostatic bath (NOVA ÉTICA  
170 521/2D). The system was subjected to mechanical stirring (using FISATOM 710) at 500 rpm.  
171 The working volume applied was 250 mL.

172 For the analysis of H<sub>2</sub>O<sub>2</sub> electro-generation, the study initially investigated the role of  
173 different current densities (25, 50, 75, and 100 mA cm<sup>-2</sup>), applied from a MetrohmAutolab  
174 PGSTAT-302N Potentiostat, over a period of 120 min in Na<sub>2</sub>SO<sub>4</sub>, where the same ionic  
175 strength and pH of synthetic urine were employed. Subsequently, the concentration of H<sub>2</sub>O<sub>2</sub>  
176 accumulated in Na<sub>2</sub>SO<sub>4</sub> was compared with that generated *in situ* within the synthetic urine  
177 matrix, both in the presence and absence of organic compounds, but under the same pH and  
178 ionic strength conditions. All the experiments were performed in duplicate, and the average  
179 measurements obtained were presented in the study.

180

## 181 2.3 Electrochemical oxidation of the main organic compounds in the synthetic urine 182 matrix

183

184 Under specific current density conditions, the electrochemical oxidation (EO) process  
185 was applied for the treatment of synthetic urine with and without the *in situ* generation of  
186 H<sub>2</sub>O<sub>2</sub> in the synthetic urine matrix; the two treatment mechanisms were referred to as  
187 EO+H<sub>2</sub>O<sub>2</sub> and EO, respectively. The study also analyzed the parallel degradation of the

188 following organic compounds in the synthetic urine matrix: urea, creatinine, and uric acid. For  
 189 the EO process, N<sub>2</sub>, employed at the same flow rate applied for O<sub>2</sub>, was used to prevent H<sub>2</sub>O<sub>2</sub>  
 190 formation.

191

## 192 2.4. Analytical techniques and efficiency analysis

193

194 H<sub>2</sub>O<sub>2</sub> was quantified using UV-Vis absorption spectrophotometry (SHIMADZU UV-  
 195 1900), where ammonium molybdate was used as the reagent [28]. The energy consumption  
 196 (*EC*) associated with the quantification of H<sub>2</sub>O<sub>2</sub> was determined using Eq. 3. The current  
 197 efficiency (*CE*) was estimated based on Faraday's law, as shown in Eq. 4.

198

$$199 \quad EC \text{ (kWh Kg}^{-1}\text{)} = 1000 \frac{E I t}{V_s C_{H_2O_2}} \quad (\text{Eq. 3})$$

$$200 \quad CE_{H_2O_2}(\%) = \frac{2 F C_{H_2O_2} V_s}{I t} \quad (\text{Eq. 4})$$

201

202 Where *E* is the average cell potential (*V*), *I* is the applied current (*A*), *t* is the time (*h*), *V<sub>s</sub>* is the  
 203 working volume (*L*), and *C<sub>H<sub>2</sub>O<sub>2</sub></sub>* is the concentration of H<sub>2</sub>O<sub>2</sub> generated (mgL<sup>-1</sup>), 2 is the  
 204 number of electrons involved in the reduction of one molecule of oxygen to produce H<sub>2</sub>O<sub>2</sub>,  
 205 and *F* represents Faraday's constant (96,487 Cmol<sup>-1</sup>).

206 The degradation of uric acid and creatinine was monitored by high-performance liquid  
 207 chromatography (HPLC-UVC) using a Shimadzu 20A HPLC system. The analytical column  
 208 had a C18 stationary phase with a particle size of 5 μm and dimensions of 4.6 mm × 150 mm,  
 209 and was kept at a constant temperature of 30°C. The experiments were conducted using a  
 210 fixed injection volume of 20 μL (of the sample). For the analysis of uric acid concentration, a  
 211 mobile phase consisting of 75:25 (v/v) phosphoric acid (0.1%) and methanol was eluted at a  
 212 flow rate of 1.0 mLmin<sup>-1</sup>, with UV absorbance (*λ*) measured at 274 nm. For the analysis of  
 213 creatinine concentration, a mobile phase of methanol/water in the ratio of 65:35 (v/v) was  
 214 employed at a flow rate of 0.5 mLmin<sup>-1</sup>, with UV absorbance (*λ*) measured at 234 nm. All the  
 215 samples were filtered using Chromafil® Xtra PET-45/25 filters with a pore size of 0.45 μm.  
 216 Urea concentration was determined using a colorimetric method described in the literature  
 217 [29]. In this method, solutions containing urea developed a yellow-green color upon reacting  
 218 with the indicator reagent, p-dimethylaminobenzaldehyde. Absorbance measurements were  
 219 performed using a spectrophotometer at the wavelength of 420 nm.

220 The degradation percentage obtained for all the quantified compounds was calculated  
 221 using Eq. 5, where *c<sub>0</sub>* represents the initial concentration, and *c<sub>t</sub>* is the concentration at a given  
 222 electrolysis time.

$$223 \quad \text{Degradation (\%)} = \frac{c_0 - c_t}{c_0} 100 \quad (\text{Eq. 5})$$

224 The amount of energy consumed ( $EC$ ) per unit volume of the treated effluent was  
 225 determined using Eq. 6, where  $E_{cell}$  is the average cell potential (V),  $t$  is the electrolysis time  
 226 (h),  $V_s$  is the solution volume ( $m^3$ ), and  $I$  is the current (A).

227

$$228 \quad EC (Wh m^{-3}) = \frac{E_{cell} I t}{V_s} \quad (\text{Eq. 6})$$

229 Total organic carbon (TOC) was analyzed using a Shimadzu TOC-L Series carbon  
 230 analyzer. The mineralization of the urine solutions was analyzed by monitoring the  
 231 percentage reduction in TOC, which was calculated using Eq. 7, where  $TOC_0$  represents the  
 232 initial measurement, and  $TOC$  is the value at electrolysis time  $t$ . Energy consumption was also  
 233 evaluated per unit mass of TOC ( $EC_{TOC}$ ) and calculated using Eq. 8, where, in addition to the  
 234 description of the parameters described in Eq. 6,  $\Delta(TOC)$  represents the content of reduced  
 235 TOC.

236

$$237 \quad \text{TOC removal (\%)} = \frac{TOC_0 - TOC}{TOC_0} 100 \quad (\text{Eq. 7})$$

$$238 \quad EC_{TOC} (kWh (g \text{ TOC})^{-1}) = \frac{E_{cell} I t}{V_s \Delta(TOC)} \quad (\text{Eq. 8})$$

239

240 The kinetic analysis conducted using the plots of  $c_0/c_t$  as a function of time  
 241 consistently pointed to a pseudo-first-order reaction, in line with Eq. 9. In this equation,  $c_0$   
 242 denotes the initial concentration,  $c_t$  is the concentration at time  $t$ , and  $k_t$  is the rate constant for  
 243 each organic compound.

244

$$245 \quad \ln \left( \frac{c_0}{c_t} \right) = k_t \times t \quad (\text{Eq. 9})$$

246

247 Carboxylic acids and most of the inorganic ions were identified using ion exchange  
 248 chromatography with Metrohm Professional IC 850 chromatograph coupled to a Professional  
 249 IC 940 module. The analysis was conducted using an injection volume of 20  $\mu\text{L}$  of each  
 250 sample. Carboxylic acids were measured using a MetrosepA Supp 5 column, with 0.5  $\text{mmol}$   
 251  $\text{L}^{-1}$   $\text{H}_2\text{SO}_4$  as the eluent. The retention times identified in the chromatograms exhibited well-  
 252 defined peaks that corresponded to oxalic acid, maleic acid, formic acid, and acetic acid.  
 253 Nitrogen anions, including nitrite ( $\text{NO}_2^-$ ) and nitrate ( $\text{NO}_3^-$ ), as well as active chlorine  
 254 species, specifically chloride ( $\text{Cl}^-$ ), chlorite ( $\text{ClO}_2^-$ ) and chlorate ( $\text{ClO}_3^-$ ), were analyzed  
 255 using a MetrosepA Supp 5 column (150  $\text{mm} \times 4.0 \text{ mm}$ ) with 3.2  $\text{mmol L}^{-1}$   $\text{Na}_2\text{CO}_3$  and 1.0  
 256  $\text{mmol L}^{-1}$   $\text{NaHCO}_3$  employed as the eluent, at a flow rate of 0.7  $\text{mL min}^{-1}$  and at the  
 257 temperature of 25°C.

258 Ammonium cation ( $\text{NH}_4^+$ ) and hypochlorite anion ( $\text{ClO}^-$ ) were identified by UV-Vis  
259 spectroscopy.  $\text{NH}_4^+$  was identified by the addition of 1 mol  $\text{L}^{-1}$  NaOH, 5%  $\text{C}_7\text{H}_6\text{O}_3$ , 5%  
260  $\text{Na}_3\text{C}_6\text{H}_5\text{O}_7$ , 0.05 mol $\text{L}^{-1}$  NaClO, and 1% sodium nitroferricyanide which led to the formation  
261 of a green complex; absorbance was measured at 655 nm [30].  $\text{ClO}^-$  was identified when the  
262 solutions were in contact with 3 mol  $\text{L}^{-1}$  NaOH; absorbance was measured at 293 nm. The pH  
263 of the solutions was measured using Ion pHB500 pH meter, while conductivity was measured  
264 using a Digimed DM-3 conductivity meter.

265

### 266 3. Results and discussion

#### 267 3.1. Analyzing the effects of current density on *in situ* $\text{H}_2\text{O}_2$ electro-generation in $\text{Na}_2\text{SO}_4$ 268 using GDE/PL6C

269

270 A number of studies conducted to specifically investigate the effects of current density  
271 have shown that this parameter is a determining factor in electrochemical processes, as it  
272 significantly affects the generation of oxidants such as  $\text{H}_2\text{O}_2$  [23,26]. A thorough analysis of  
273 this parameter is essential for optimizing these processes, as this helps enhance the efficiency  
274 and the economic feasibility of wastewater treatment systems. To better understand the effects  
275 of current density on the efficiency of the treatment system, GDE/PL6C was used for  $\text{H}_2\text{O}_2$   
276 electro-generation initially in  $\text{Na}_2\text{SO}_4$  under ionic strength and pH conditions similar to those  
277 of synthetic urine (specifically 0.3 mol  $\text{L}^{-1}$  and pH = 5.26, respectively). Electrolysis tests  
278 were performed at current densities of 25, 50, 75, and 100  $\text{mA cm}^{-2}$  in order to evaluate the  
279 performance and efficiency of the electrodes (Figure 2a). The results obtained from the  
280 monitoring of  $\text{H}_2\text{O}_2$  concentration over time at different current densities showed a clear  
281 pattern:  $\text{H}_2\text{O}_2$  production increases as current density increases. The doubling of the current  
282 density from 25 to 50  $\text{mA cm}^{-2}$  resulted in an almost 2-fold increase in the concentration of  
283  $\text{H}_2\text{O}_2$  accumulated in the system. A similar pattern of behavior was also observed when the  
284 current densities of 75  $\text{mA cm}^{-2}$  and 100  $\text{mA cm}^{-2}$  were applied; these current densities  
285 promoted an increase in  $\text{H}_2\text{O}_2$  production of roughly 3 and 4-fold, respectively, in the system.  
286 These results show that the concentration of  $\text{H}_2\text{O}_2$  produced in the system was directly  
287 proportional to the applied current density; this outcome can be attributed to an increase in the  
288 electron transfer rate at the electrode/solution interface, which favors the  $2e^-$  reduction of  
289 molecular oxygen to  $\text{H}_2\text{O}_2$  at the cathode (see Eq. 1) [31].

290 Figure 2b supports the aforementioned behavioral pattern observed in the system; the  
291 figure shows that the kinetic constant for  $\text{H}_2\text{O}_2$  production ( $k$ ), calculated during the first 30  
292 min of electrolysis, increases when the applied current density is increased. However, the  
293 linear relationship between these two parameters is not directly proportional across the entire  
294 time range and for all current densities. For instance, a 4-fold increase in the current density  
295 (from 25 to 100  $\text{mA cm}^{-2}$ ) resulted in a 7-fold increase in  $k$  (from 4.3345  $\text{mg L}^{-1} \text{min}^{-1}$  to  
296 28.6950  $\text{mg L}^{-1} \text{min}^{-1}$ ); this outcome suggests that although the experimental data fits well  
297 with pseudo-first-order kinetics, with  $R^2$  values between 0.97 and 0.99, there is a slight  
298 deviation from ideal kinetics, particularly at higher current densities. This deviation could be  
299 related to operational factors, such as limited diffusion. At higher current densities, the  
300 reaction rate may exceed the rate of  $\text{O}_2$  diffusion to the electrode surface, leading to mass

301 transfer limitations and creating a concentration gradient that hinders H<sub>2</sub>O<sub>2</sub> generation during  
302 the first 30 min of electrolysis [32,33].

303 Given the observed deviation in H<sub>2</sub>O<sub>2</sub> production kinetics at higher current densities, it  
304 is essential to evaluate the effects of current density on energy consumption and current  
305 efficiency in order to gain a more comprehensive understanding of the operational feasibility  
306 of the treatment system. The EC and CE associated with the electro-generation of H<sub>2</sub>O<sub>2</sub> were  
307 calculated under the current densities investigated, and the results obtained are presented in  
308 Figure 2c. It can be seen that, as the current density increases, there is a significant rise in  
309 energy consumption, from 65.99 kWh kg<sup>-1</sup> at 25 mA cm<sup>-2</sup> to 193.27 kWh kg<sup>-1</sup> at 100 mA cm<sup>-2</sup>.  
310 This increase in energy consumption is expected, since the application of higher current  
311 densities leads to more power being applied to the system, and this essentially raises the total  
312 energy consumed per unit mass of H<sub>2</sub>O<sub>2</sub> produced [26].

313 On the other hand, the current efficiency shows a slight decline with increasing current  
314 density, dropping from 10.17% at 25 mA cm<sup>-2</sup> to 9.38% at 100 mA cm<sup>-2</sup>. This reduction in CE  
315 observed for higher current densities can be attributed to factors such as the occurrence of  
316 undesired parallel reactions, including oxygen evolution (Eq. 10) and/or the direct reduction  
317 of O<sub>2</sub> to H<sub>2</sub>O via the 4e<sup>-</sup> pathway (Eq. 11) in acidic media [20]. These factors may contribute  
318 to a decrease in the proportion of electrons that effectively contribute to H<sub>2</sub>O<sub>2</sub> production,  
319 reducing the conversion efficiency. Thus, while increasing the current density results in  
320 higher H<sub>2</sub>O<sub>2</sub> production, it comes at the cost of greater energy consumption and a slight  
321 reduction in current efficiency.

322

326

327 These results point to the need to optimize the applied current density so as to secure a  
328 balance between efficient H<sub>2</sub>O<sub>2</sub> production and energy consumption. Thus, the current density  
329 of 50 mA cm<sup>-2</sup> was selected for the conduct of subsequent studies. The choice of this current  
330 density was primarily driven by the central goal of this work, which is the treatment of  
331 synthetic urine. Given that urine is a complex matrix, it is essential to adopt a moderate  
332 current density that can help overcome the inherent challenges brought about by the matrix  
333 complexity while promoting the effective degradation of the compounds present there in [15].  
334 Although the current efficiency recorded for 50 mA cm<sup>-2</sup> is slightly lower than that of 25 mA  
335 cm<sup>-2</sup>, the application of the chosen current density (50 mA cm<sup>-2</sup>) can help ensure the  
336 accumulation of a significant H<sub>2</sub>O<sub>2</sub> concentration in the synthetic urine matrix.

337

338 **3.2. Understanding the mechanism involving the *in situ* electro-generation and**  
339 **accumulation of H<sub>2</sub>O<sub>2</sub> in synthetic urine matrix**

340

341 The compositional complexity of synthetic urine presents additional challenges for the  
342 application of electrochemical treatment processes. In addition to organic compounds, this  
343 effluent contains a wide range of ionic species that can influence the efficiency of H<sub>2</sub>O<sub>2</sub>  
344 generation. To have a clearer understanding of the effects of the matrix, a comparative  
345 analysis was conducted in order to compare the concentration of H<sub>2</sub>O<sub>2</sub> electrogenerated at 50  
346 mA cm<sup>-2</sup> in Na<sub>2</sub>SO<sub>4</sub> with H<sub>2</sub>O<sub>2</sub> concentration generated in the synthetic urine matrix, both in  
347 the presence and absence of organic compounds; in this study, we refer to the matrix  
348 containing organic compounds as synthetic urine matrix and the one without organic  
349 compounds as synthetic inorganic urine matrix. For comparative purposes, the same ionic  
350 strength and pH were employed in the matrices investigated.

351 Figure 3a shows the concentration of H<sub>2</sub>O<sub>2</sub> generated in the matrices investigated over  
352 120 min of electrolysis. It is observed that throughout the entire period of electrolysis, the  
353 concentration of H<sub>2</sub>O<sub>2</sub> produced followed this order: Na<sub>2</sub>SO<sub>4</sub> > synthetic urine matrix >  
354 synthetic inorganic urine matrix. The results obtained point to a significant influence of the  
355 compositional complexity of the urine matrix on the efficiency of the H<sub>2</sub>O<sub>2</sub> generation  
356 process. The Na<sub>2</sub>SO<sub>4</sub> solution, used as a simple reference matrix, yielded approximately 505  
357 mg L<sup>-1</sup> of H<sub>2</sub>O<sub>2</sub> after 120 min of electrolysis. However, when the synthetic urine matrix  
358 containing organic compounds - including urea, creatinine, and uric acid, was employed, the  
359 concentration of H<sub>2</sub>O<sub>2</sub> generated was reduced to 175 mg L<sup>-1</sup> by the end of the process. This  
360 substantial decrease in H<sub>2</sub>O<sub>2</sub> production can be attributed to the presence of organic  
361 compounds in the urine, which consume H<sub>2</sub>O<sub>2</sub> in the degradation process or compete for the  
362 same electrons that would be used in the reduction of molecular oxygen to form H<sub>2</sub>O<sub>2</sub>. This  
363 behavior is further supported by the fact that, after 45 min of electrolysis, there is a  
364 stabilization in the concentration of H<sub>2</sub>O<sub>2</sub> produced in the synthetic urine matrix (which  
365 contains organic compounds); this phenomenon can be attributed to the chemical equilibrium  
366 established between the H<sub>2</sub>O<sub>2</sub> formation reactions at the cathode and the H<sub>2</sub>O<sub>2</sub> degradation  
367 reactions at the anode [26,34].

368 When the organic compounds were removed from the synthetic urine matrix; i.e.,  
369 when the synthetic inorganic urine matrix was employed, there was a further reduction in the  
370 concentration of H<sub>2</sub>O<sub>2</sub> generated, with H<sub>2</sub>O<sub>2</sub> production beginning only after 15 min of  
371 electrolysis and reaching a mere 61.3 mg L<sup>-1</sup> by the end of the process. These results are  
372 evidently surprising and go counter to our initial expectation that the concentration of H<sub>2</sub>O<sub>2</sub>  
373 generated in the synthetic inorganic urine matrix would be greater than that of the synthetic  
374 urine matrix (containing organic compounds). This observation suggests that, in addition to  
375 the organic compounds, the ionic composition of the urine itself exerts a significant effect on  
376 the efficiency of H<sub>2</sub>O<sub>2</sub> electrogeneration, as the complex mixture of ions may influence the  
377 reactions at the electrode/solution interface. Another explanation for this unexpected outcome  
378 is that, in the absence of organic compounds, the active species formed in the inorganic  
379 reaction medium (synthetic inorganic urine matrix), such as active chlorine species, are free to  
380 act as H<sub>2</sub>O<sub>2</sub> scavengers. In other words, without the presence of organic matter to be  
381 degraded, these active species, which would typically participate in the degradation of organic  
382 compounds, end up more intensely capturing and decomposing the H<sub>2</sub>O<sub>2</sub> generated.

383 Through a careful analysis of the data on energy consumption and current efficiency  
384 (Figure 3b), one is able to have a better understanding of the mechanism involving the  
385 efficiency of H<sub>2</sub>O<sub>2</sub> electro-generation in urine matrices and the effect of their complex nature  
386 on the efficiency of the treatment system. The application of the Na<sub>2</sub>SO<sub>4</sub> solution as the

387 reaction medium resulted in the lowest energy consumption (113.45 kWh kg<sup>-1</sup>) and the  
388 highest current efficiency (9.96%). These results point to the effectiveness of the GDE/PL6C  
389 and the electrochemical system when applied to a less complex solution, where the H<sub>2</sub>O<sub>2</sub>  
390 generation reaction occurs more efficiently, with reduced energy loss which stems from  
391 secondary reactions or resistive effects. However, the *in situ* electro-generation of H<sub>2</sub>O<sub>2</sub> in the  
392 synthetic urine matrix, which, in addition to Na<sub>2</sub>SO<sub>4</sub>, contains NaCl, KCl, NaH<sub>2</sub>PO<sub>4</sub>, and  
393 organic compounds including urea, creatinine, and uric acid, led to more than a 2-fold  
394 increase in energy consumption (277.12 kWh kg<sup>-1</sup>), while current efficiency decreased to  
395 3.27%. These results can be attributed to the presence of organic compounds that consume  
396 H<sub>2</sub>O<sub>2</sub> during the degradation process or compete for electrons, diverting the action of the  
397 current toward parallel reactions. When the synthetic inorganic urine matrix was used as the  
398 reaction medium, there was a significant increase in energy consumption (725.92 kWh kg<sup>-1</sup>),  
399 while current efficiency dropped to 1.21%. This outcome helps confirm that the high ionic  
400 complexity of the synthetic urine matrix undermines the overall efficiency of the H<sub>2</sub>O<sub>2</sub>  
401 generation process; in essence, this highlights the need to investigate each compound  
402 separately so as to have a better understanding of their effects, thus contributing toward  
403 optimizing the electro-sanitation treatment process.

404

### 405 **3.3 Unraveling the influence of the compositional complexity of synthetic inorganic urine** 406 **matrix on the electro-generation of H<sub>2</sub>O<sub>2</sub>**

407

408 As pointed out previously, the complexity of the synthetic inorganic urine matrix  
409 poses a significant challenge to the electrogeneration of H<sub>2</sub>O<sub>2</sub>; this challenge arises because  
410 the ions present in this matrix, including SO<sub>4</sub><sup>2-</sup>, Cl<sup>-</sup>, and PO<sub>4</sub><sup>3-</sup>, can interact with H<sub>2</sub>O<sub>2</sub>,  
411 reducing its availability in the medium and/or promoting competitive reactions. With this in  
412 mind, and to identify which of these compounds act as true interferents, H<sub>2</sub>O<sub>2</sub> generation was  
413 analyzed individually for each of the constituent salts in the urine matrices. This analysis was  
414 conducted using the same ionic strength and pH of synthetic urine at a current density of 50  
415 mA cm<sup>-2</sup> over a period of 120 min of electrolysis. Figure 4 presents a comparative analysis of  
416 the concentration of H<sub>2</sub>O<sub>2</sub> generated in NaCl, KCl, and NaH<sub>2</sub>PO<sub>4</sub> compared to that generated  
417 in Na<sub>2</sub>SO<sub>4</sub> and in the urine matrices investigated.

418 The results obtained showed significant variations in the concentration of H<sub>2</sub>O<sub>2</sub>  
419 generated over the electrolysis time in the different electrolytes (of synthetic urine) employed.  
420 When Na<sub>2</sub>SO<sub>4</sub> was applied, there was a consistent increase in H<sub>2</sub>O<sub>2</sub> generation over time. A  
421 much lower H<sub>2</sub>O<sub>2</sub> production was recorded for KCl, where only 50.8 mg L<sup>-1</sup> was produced at  
422 the end of 120 min of electrolysis. NaCl, in contrast, exhibited intermediate production levels,  
423 yielding 70.5 mg L<sup>-1</sup> of H<sub>2</sub>O<sub>2</sub> over the same period. Interestingly, NaH<sub>2</sub>PO<sub>4</sub> recorded the  
424 highest concentration of H<sub>2</sub>O<sub>2</sub> produced, reaching stabilization in around 30 min of  
425 electrolysis, and accumulating approximately 330 mg L<sup>-1</sup> of H<sub>2</sub>O<sub>2</sub> after 120 min of  
426 electrolysis.

427 The results obtained show that distinct chemical interactions impact the efficiency of  
428 the electrochemical process; in general terms, the results suggest that KCl and NaCl act more  
429 intensely as inhibitors in the generation of H<sub>2</sub>O<sub>2</sub> compared to NaH<sub>2</sub>PO<sub>4</sub> and Na<sub>2</sub>SO<sub>4</sub>. When

430 one focuses the analysis on the isolated anionic species, the results imply that the higher  
 431 generation of H<sub>2</sub>O<sub>2</sub> in Na<sub>2</sub>SO<sub>4</sub> (Figure 4a) can be attributed to the fact that the sulfate anion  
 432 (SO<sub>4</sub><sup>2-</sup>) does not significantly interfere with the oxygen reduction process at the electrode  
 433 surface, and this allows for a more efficient conversion of O<sub>2</sub> to H<sub>2</sub>O<sub>2</sub>. However, it is  
 434 important to note that although sulfate is considered an inert anion when it comes to H<sub>2</sub>O<sub>2</sub>  
 435 generation for comparative purposes in this study, the production of peroxomonosulfate  
 436 (SO<sub>5</sub><sup>2-</sup>) can also occur during the electrochemical process involving the use of GDE/PL6C, as  
 437 shown in Eq. 12. SO<sub>5</sub><sup>2-</sup> is regarded as a predatory species of H<sub>2</sub>O<sub>2</sub> which reacts with itself, as  
 438 indicated in Eq. 13 [23].

443

444         Regarding NaH<sub>2</sub>PO<sub>4</sub>, as demonstrated in Figure 4a, the relatively lower concentration  
 445 of H<sub>2</sub>O<sub>2</sub> generated compared to that produced in Na<sub>2</sub>SO<sub>4</sub> can be explained by the reaction  
 446 between the dihydrogen phosphate ion (H<sub>2</sub>PO<sub>4</sub><sup>-</sup>) and H<sub>2</sub>O, which leads to the formation of  
 447 hydroxyl radicals (<sup>•</sup>OH), as shown in Eq. 14 and Eq. 15 [14,35]. This mechanism suggests  
 448 that, although a direct reaction between H<sub>2</sub>PO<sub>4</sub><sup>-</sup> and H<sub>2</sub>O<sub>2</sub> is uncommon, the higher <sup>•</sup>OH  
 449 concentrations present in the solution may react with the H<sub>2</sub>O<sub>2</sub> generated, converting it into  
 450 H<sub>2</sub>O (Eq.16), and thereby reducing the availability of H<sub>2</sub>O<sub>2</sub> in the medium. Furthermore,  
 451 phosphate may form complexes that accelerate the decomposition of H<sub>2</sub>O<sub>2</sub> and may also play  
 452 a dual role in generating reactive oxygen species (ROS) that facilitate the formation of  
 453 O<sub>2</sub><sup>•-</sup> and alter the pathway of <sup>•</sup>OH formation, further decreasing the concentration of H<sub>2</sub>O<sub>2</sub> in  
 454 the treated solution [36]. The stabilization observed in H<sub>2</sub>O<sub>2</sub> production after 30 min of  
 455 electrolysis can be attributed precisely to the phosphate ability to form these complexes,  
 456 which, in interaction with other anionic species and/or intermediate radical species, can  
 457 diminish the decomposition of H<sub>2</sub>O<sub>2</sub> and stabilize its concentration in the solution.

464

465 On the other hand, the accumulated concentration of H<sub>2</sub>O<sub>2</sub> recorded in KCl and NaCl  
 466 was significantly lower than that recorded in Na<sub>2</sub>SO<sub>4</sub> after 120 min of electrolysis (results are  
 467 more clearly visible in the scale of Figure 4b). This phenomenon observed in chloride media  
 468 can be attributed to the influence of active chlorine species formation. It has been well  
 469 documented in the literature that the oxidation of chloride ion (Cl<sup>-</sup>) on the anode surface leads  
 470 to the generation of chlorine (Cl<sub>2(aq)</sub>, E°= 1.36 V vs SHE), as shown in Eq. 17. Chlorine  
 471 subsequently undergoes hydrolysis to produce hypochlorous acid (HClO, E°= 1.49 V vs SHE)  
 472 and Cl<sup>-</sup>, as per Eq. 18. Under specific speciation conditions (pKa = 7.55), HClO enters an  
 473 acid-base equilibrium, and this leads to the production of hypochlorite (OCl<sup>-</sup>, E° = 0.89 V vs  
 474 SHE), as demonstrated in Eq. 19. After the occurrence of this reaction, the active chlorine  
 475 species consume H<sub>2</sub>O<sub>2</sub> through secondary reactions, as exemplified in Eqs. 20, 21, and 22,  
 476 respectively, for Cl<sub>2</sub>, HOCl, and OCl<sup>-</sup> [37–39].

489

490 In summary, for the electro-generation and accumulation of H<sub>2</sub>O<sub>2</sub> in the synthetic  
 491 inorganic urine matrix, which is specifically constituted by Na<sub>2</sub>SO<sub>4</sub>, NaCl, KCl, and  
 492 NaH<sub>2</sub>PO<sub>4</sub>, as previously discussed, we found that this matrix yielded a relatively lower  
 493 concentration of H<sub>2</sub>O<sub>2</sub> compared to Na<sub>2</sub>SO<sub>4</sub> and the other media studied individually. This  
 494 behavior shows that an increase in the complexity of the reaction medium contributes to the  
 495 reduction in the concentration of H<sub>2</sub>O<sub>2</sub> generated; this is likely due to increased parasitic  
 496 reactions involving inorganic ions and/or other causes mentioned previously. These results  
 497 point to the complexity of the synthetic urine matrix when used in the electro-generation of  
 498 H<sub>2</sub>O<sub>2</sub>; in essence, the results suggest that, in order to optimize H<sub>2</sub>O<sub>2</sub> production in wastewater  
 499 treatment systems involving urine, it is essentially crucial to have a thorough understanding of  
 500 the synergistic and inhibitory effects of the various compounds present in the matrix, and of

501 other related factors. Thus, having a comprehensive understanding of the processes involving  
502 the degradation and mineralization of organic compounds in urine through electrochemical  
503 oxidation with and without *in situ* H<sub>2</sub>O<sub>2</sub> generation is crucial for devising efficient strategies  
504 for the treatment of sanitary wastewater.

505

### 506 **3.4. *In situ* generated H<sub>2</sub>O<sub>2</sub> in synthetic urine and its effect on the degradation and** 507 **mineralization of organic matter**

508

509 Urine is a matrix of complex composition, and the presence of organic compounds,  
510 such as urea, creatinine, and uric acid, in it presents additional challenges for electrochemical  
511 treatment processes. Understanding the potential of *in situ* generated H<sub>2</sub>O<sub>2</sub> in degrading these  
512 compounds in the urine matrix is essential for developing effective electro-sanitation  
513 treatment strategies. Figure 5a shows the parallel degradation percentages obtained for the  
514 organic compounds present in urine during the electrochemical process based on the  
515 application of the GDE/PL6C cathode in the presence (EO+H<sub>2</sub>O<sub>2</sub>) and absence of H<sub>2</sub>O<sub>2</sub>  
516 generation (EO) at the current density of 50 mA cm<sup>-2</sup>. It is worth noting that, in the EO  
517 process, N<sub>2</sub> was injected into the GDE/PL6C, instead of O<sub>2</sub>, equivalent to 0.05 Lmin<sup>-1</sup>. The  
518 results obtained pointed to significant differences between the EO+H<sub>2</sub>O<sub>2</sub> and EO processes, in  
519 terms of the degradation and mineralization of organic compounds in urine; importantly, the  
520 results show that H<sub>2</sub>O<sub>2</sub> was effectively beneficial for the degradation of urea and creatinine.

521 Urea (CH<sub>4</sub>N<sub>2</sub>O) is the predominant organic compound in human urine; its structure is  
522 quite dynamic, and the compound can exhibit various conformational variations when in  
523 aqueous solution [40]. As illustrated in Figure 5a, urea is the organic compound that was  
524 found to be the most resistant to degradation in the EO+H<sub>2</sub>O<sub>2</sub> and EO processes; the  
525 application of the EO+H<sub>2</sub>O<sub>2</sub> and EO processes led to urea degradation of 43.4% and 35.1%,  
526 respectively, after 120 min of electrolysis. The lower removal of urea compared to other  
527 compounds may be attributed to competitive degradation among the co-existing compounds.  
528 Furthermore, considering that urea is present in much higher concentration in the medium,  
529 approximately 20 times more than creatinine and 65 times more than uric acid, it is likely that  
530 greater rates of urea removal would require longer treatment times. The percentage difference  
531 in urea degradation observed between the EO+H<sub>2</sub>O<sub>2</sub> and EO processes was 8.3%. Although  
532 this percentage is relatively low, it represents approximately 273.0 mg L<sup>-1</sup> in absolute terms;  
533 this shows that the presence of *in situ* generated H<sub>2</sub>O<sub>2</sub> in urine has a positive effect on urea  
534 degradation. These observed improvements in the compounds degradation efficiency provide  
535 us with useful insights into the development of more effective strategies for the treatment of  
536 sanitary effluents, where urea is one of the primary pollutants to be degraded.

537 Another relevant point that deserves mentioning is that H<sub>2</sub>O<sub>2</sub> can also be explored as  
538 an inhibitor of the process involving the hydrolysis of urea in real urine systems [41]. This is  
539 particularly relevant given the inherent instability of urea, which rapidly decomposes in the  
540 presence of urease, an enzyme commonly found in urine collection systems. During this  
541 process, urea breaks down into ammonium ions and bicarbonate, as described in Eq. 23  
542 [42,43]; this enzyme is naturally present in both urine and the environment [8]. After the  
543 hydrolysis process, the pH of the medium increases to a value above 9.0 [44]. The inactivation

544 of urease by H<sub>2</sub>O<sub>2</sub> in real urine systems - which blocks the hydrolysis of urea, prevents the  
545 increase in soil pH and consequently reduces the risk of eutrophication in water bodies, as  
546 well as the release of free ammonia into the atmosphere [45].

547

549

550 Regarding creatinine (C<sub>4</sub>H<sub>7</sub>N<sub>3</sub>O) - the second most abundant compound in the urine  
551 matrix, Figure 5a shows that both treatment processes tested in the study were effective in  
552 degrading it, with 77.2% and 68.6% creatinine degradation recorded for EO+H<sub>2</sub>O<sub>2</sub> and EO  
553 processes, respectively. We noted that the treatment process that involved H<sub>2</sub>O<sub>2</sub> electro-  
554 generation (EO+H<sub>2</sub>O<sub>2</sub>) was 8.6% more efficient; in other words, this process was able to  
555 remove an additional 14.3 mg L<sup>-1</sup> of creatinine compared to the process without H<sub>2</sub>O<sub>2</sub>  
556 generation. Although the observed difference is relatively smaller in comparison with urea  
557 degradation, it still shows that the presence of *in situ* generated H<sub>2</sub>O<sub>2</sub> enhances the oxidation  
558 process. The higher rate of degradation of creatinine relative to urea may be attributed to the  
559 following: lower concentration of creatinine in the matrix, and competitive oxidation with  
560 other compounds present in the synthetic urine matrix [15].

561 On the other hand, the degradation of uric acid (C<sub>5</sub>H<sub>5</sub>N<sub>4</sub>O<sub>3</sub>) - the smallest organic  
562 compound in the synthetic urine matrix, was satisfactorily efficient in both the EO+H<sub>2</sub>O<sub>2</sub> and  
563 EO processes, since both processes recorded 100% uric acid removal, as shown in Figure 5a.  
564 These findings show that the electrochemical oxidation process alone is sufficient for the  
565 degradation of uric acid in the synthetic urine matrix, and that H<sub>2</sub>O<sub>2</sub> may not be necessary for  
566 the complete degradation of the compound. However, H<sub>2</sub>O<sub>2</sub> can play a complementary role,  
567 particularly in scenarios where the matrix is more complex or where other compounds may  
568 interfere with the process efficiency, especially in the degradation of by-products or  
569 intermediate compounds generated during the oxidation of uric acid. These results are  
570 consistent with previous studies reported in the literature which have demonstrated the  
571 efficiency of the electrochemical oxidation process when applied for the degradation of uric  
572 acid in urine [15,46–48]. The system preference for the degradation of uric acid over urea and  
573 creatinine may be due to the presence of multiple functional groups in the structure of uric  
574 acid [46].

575 In some literature studies, in addition to EO and EO+H<sub>2</sub>O<sub>2</sub>, other advanced processes  
576 have been explored for the treatment of synthetic urine, particularly for the removal of  
577 pharmaceuticals in this effluent. Goulart et al. demonstrated that photolysis and  
578 photoelectrolysis were effective in the degradation of the antibiotic levofloxacin in synthetic  
579 urine, while showing that creatinine and uric acid were degraded together with the antibiotic  
580 during the processes [46]. Similarly, Gonzaga et al. reported that the Electro-Fenton (EF) and  
581 Photoelectro-Fenton (PhEF) processes are also viable technologies for the treatment of  
582 synthetic urine contaminated with Penicillin G. In their study, the authors showed that the  
583 PhEF process was more efficient than EF in the degradation of the pharmaceutical, with the  
584 best results achieving complete degradation in synthetic urine [49].

585 The analysis of the operational costs of the treatment system, particularly energy  
586 demand, is crucial when it comes to assessing the efficiency of the technologies employed for  
587 wastewater treatment and the degradation of unwanted organic pollutants [50]. The energy  
588 consumed per volume of the treated effluent in the EO and EO+H<sub>2</sub>O<sub>2</sub> processes was estimated  
589 using Eq. 5; the results obtained are presented in Figure 5b. As can be observed, the results  
590 show that in order to remove 43.4% of urea, 77.2% of creatinine, and 100% of uric acid, the  
591 EO+H<sub>2</sub>O<sub>2</sub> process consumed 46.32 kWh dm<sup>-3</sup> of energy; in contrast, the EO process required  
592 56.18 kWh dm<sup>-3</sup> to remove the same percentage of uric acid and relatively lower percentages  
593 of urea and creatinine compared to the EO+H<sub>2</sub>O<sub>2</sub> process. This increase in energy  
594 consumption of nearly 10 kWh dm<sup>-3</sup> in the EO process further underscores the importance of  
595 H<sub>2</sub>O<sub>2</sub> in enhancing the overall efficiency of the electrochemical process; in essence, this  
596 outcome reinforces the role of H<sub>2</sub>O<sub>2</sub> as a critical element when it comes to developing  
597 efficient wastewater treatment technologies.

598 Another fundamental analysis when it comes to evaluating the overall efficiency of  
599 electrochemical treatment techniques is the mineralization process. In complex matrices, such  
600 as the synthetic urine used in this study, having a clear understanding of the mineralization  
601 process is essential to ensuring the complete conversion of organic matter to CO<sub>2</sub>, H<sub>2</sub>O, and  
602 inorganic ions. Figure 5c shows the kinetic curve and the TOC removal rates recorded for the  
603 EO and EO+H<sub>2</sub>O<sub>2</sub> processes during 120 min of electrolysis at the current density of 50 mA  
604 cm<sup>-2</sup>. Regarding the kinetics of mineralization, the two processes exhibited a similar behavior,  
605 with no significant differences in TOC reduction up to approximately 30 min of electrolysis.  
606 After this period, the EO+H<sub>2</sub>O<sub>2</sub> process once again demonstrated higher efficiency compared  
607 to the EO process. At the end of the electrolysis, the partial mineralization achieved was  
608 31.8% and 22.5% for EO+H<sub>2</sub>O<sub>2</sub> and EO, respectively. In absolute terms, considering the  
609 presence of high TOC in the urine matrix (TOC<sub>i</sub> = 750 mg L<sup>-1</sup>), the difference in the TOC  
610 removal percentage between the processes, as indicated in Figure 5d, corresponds to 68.6 mg  
611 L<sup>-1</sup>; this value is found to be highly significant for the mineralization process and shows that  
612 H<sub>2</sub>O<sub>2</sub> also plays an influential role in mineralization. The difference between the two  
613 treatment processes is also evident in the estimated energy consumption per unit mass of TOC  
614 removed, calculated using Eq. 7 and presented in Figure 5d. Notably, the EO+H<sub>2</sub>O<sub>2</sub> process  
615 exhibited a lower energy consumption of 91.9 kWh (g TOC)<sup>-1</sup> compared to 98.1 kWh (g  
616 TOC)<sup>-1</sup> for EO alone. This reduction highlights the positive contribution of in situ H<sub>2</sub>O<sub>2</sub>  
617 generation in enhancing the process efficiency. Although the absolute values remain high, the  
618 observed decrease suggests that H<sub>2</sub>O<sub>2</sub> plays a role in facilitating organic compound  
619 degradation, ultimately leading to a more energy-efficient approach within the studied system.

620 Despite the difference in TOC removal rates observed between the EO+H<sub>2</sub>O<sub>2</sub> and EO  
621 processes, the unimpressive mineralization rate of 31.8% recorded for the EO+H<sub>2</sub>O<sub>2</sub> process  
622 can primarily be attributed to the partial degradation of urea, considering that this compound  
623 accounts for about 90% of the TOC in the matrix. Similarly, the tendency for stabilization in  
624 TOC removal observed after 45 min of electrolysis in both the EO+H<sub>2</sub>O<sub>2</sub> and EO processes  
625 (see Figure 5c) point to the formation of recalcitrant species which are resistant to the  
626 mineralization process. These findings are also consistent with previous studies [15,48,51]  
627 and point to the need for further investigation and the development of highly efficient  
628 processes for the treatment of complex and real matrices.

629 The findings highlight the importance of considering the concentration and dynamics  
630 of organic compounds in complex matrices to optimize electrochemical processes. This need

631 is particularly emphasized in real systems, where the inclusion of  $H_2O_2$  generated in situ,  
632 based on the matrix's composition, serves as an effective strategy for enhancing the removal  
633 of resistant compounds. Such an approach is especially crucial for the treatment of sanitary  
634 effluents, as *in situ* generation of  $H_2O_2$  enables decentralized treatment actions. In the case of  
635 urine, this strategy is highly recommended due to the logistical challenges of transporting  
636 large volumes of effluent to centralized systems. Consequently, these strategies not only  
637 improve the efficiency of treatment but also offer a more sustainable approach for managing  
638 wastewater, including its discharge to urban wastewater treatment plants.

639

### 640 **3.5 Kinetic analysis of the degradation of organic compounds in synthetic urine based on** 641 **the application of EO+ $H_2O_2$ and the role of active chlorine species**

642

643 The kinetic analysis of organic compounds degradation in the synthetic urine matrix  
644 under the EO+ $H_2O_2$  process is essentially crucial because it helps boost our understanding of  
645 the dynamics involving the removal of different compounds (urea, creatinine, and uric acid)  
646 which co-exist in complex systems. The organic compounds in complex matrices exhibit  
647 different reactivities toward oxidative processes, and this leads us to obtain different rates of  
648 degradation of the compounds (see Figure 5a) which occur simultaneously in the treatment  
649 system. Understanding the behavior of these co-existing compounds in the urine matrix over  
650 the course of the treatment process is essential for developing effective strategies for the  
651 treatment of sanitary effluents and for boosting their application in real systems.

652 Figure 6a shows the gradual decline in the normalized concentration of urea,  
653 creatinine, and uric acid under the EO+ $H_2O_2$  process, applied at the current density of 50 mA  
654  $cm^{-2}$  in 120 min of electrolysis. The temporal analysis indicated that the first 60 min of  
655 electrolysis were more efficient for the degradation of urea and creatinine, with approximately  
656 31% and 68% removal rates recorded for the compounds, respectively. In contrast, uric acid  
657 was more susceptible to oxidation; this compound was completely removed within the first 10  
658 min of electrolysis. The observed decrease in the process efficiency with increased  
659 electrolysis time, particularly after the initial 60 min, where an additional removal of only  
660 about 11% of urea and 8% of creatinine was recorded in the subsequent hour, may be  
661 attributed to the reduced concentration of these compounds that remained in the system. This  
662 reduction in the concentration of the compounds (urea and creatinine, in this case) leads to  
663 diminished substrate availability for oxidation reactions. As the concentrations of urea and  
664 creatinine decrease over time, competition for oxidizing species, such as  $H_2O_2$ , becomes less  
665 intense. These observations suggest that the kinetics of organic compounds degradation in  
666 urine reflect not only the individual properties of each substance but also the complex  
667 interactions occurring within the medium.

668 In real systems, where multiple organic compounds are present, the concurrent  
669 degradation of these compounds can significantly impact the efficiency of the process. This  
670 competition dynamics involving the compounds can be analyzed through a comparison of  
671 their respective rate constants [52]. Figure 6b presents the corresponding pseudo-first-order  
672 kinetic rate constants obtained for the concentration decay shown in Figure 6a. Looking at the

673 strong correlations observed up to 30 min of electrolysis, the rate constants obtained were  
674 0.0057, 0.0344, and 0.5441 min<sup>-1</sup> for urea, creatinine, and uric acid, respectively.

675 In our present study, considering the rapid decay of uric acid concentration relative to  
676 urea and creatinine, the ratio  $k_{uric\ acid}/k_n$  was used to analyze the competitive dynamics  
677 involving the organic compounds present in the synthetic urine matrix. In this analysis,  $k_n$   
678 represents the kinetic degradation constant of either urea or creatinine. A ratio > 1 indicates a  
679 preference for the degradation of uric acid over the other compounds, whereas a ratio < 1  
680 indicates the preference for the degradation of urea or creatinine over uric acid [46]. The  
681 analysis of the competitive action among the compounds yielded  $k_{uric\ acid}/k_{urea}$  ratio =  
682 95.46 and  $k_{uric\ acid}/k_{creatinine}$  ratio = 15. These results, which are consistently > 1, show  
683 that the system has a preference for the removal of uric acid over urea and creatinine, with the  
684 degradation rate of uric acid being approximately 100 times greater than that of urea and  
685 about 15 times faster than that of creatinine. Among the factors that affect the degradation  
686 process, the concentrations of the compounds play a crucial role. As previously noted, in the  
687 presence of higher initial concentration of the compounds, the system may require more time  
688 to achieve certain removal rates. In the case of uric acid, its comparatively lower  
689 concentration relative to urea and creatinine is expected to facilitate its faster degradation. In  
690 addition, the presence of multiple functional groups in uric acid may have been a determining  
691 factor for its higher and faster degradation rates.

692 It is worth noting that, in addition to direct oxidation and the action of H<sub>2</sub>O<sub>2</sub>, other  
693 species formed during the process can also act as oxidants for the organic matter present in  
694 urine. Among these species, hydroxyl radicals (<sup>•</sup>OH) and chlorinated species are particularly  
695 relevant. The diffusion of these electroactive species toward the anode plays a crucial role, as  
696 this can influence both the distribution and availability of the compounds to be degraded [15].  
697 Regarding <sup>•</sup>OH, the dimerization of DSA (<sup>•</sup>OH) can lead to the formation of H<sub>2</sub>O<sub>2</sub>, as shown  
698 in Eq. 24, and both species can subsequently react to form the hydroperoxyl radical  
699 (DSA(HO<sub>2</sub><sup>•</sup>)), a weak oxidant, as per Eq. 25[15].

700

702

704

705 Regarding chlorinated species, Cl<sup>-</sup> can be oxidized to Cl<sub>2</sub> (see Eq. 17), which can then  
706 undergo deprotonation to form ClO<sup>-</sup>, as indicated in Eq. 26. On the other hand, the ClO<sup>-</sup>  
707 generated can undergo consecutive anodic oxidation to produce ClO<sub>2</sub><sup>-</sup>, ClO<sub>3</sub><sup>-</sup> and ClO<sub>4</sub><sup>-</sup>, as  
708 described in Eqs. 27, 28, and 29, respectively[15].

709

711

713

715

717

718 In this context, thorough analyses were conducted in order to monitor the changes in  
 719 pH and  $\text{Cl}^-$  ions, as well as the evolution of  $\text{ClO}^-$ ,  $\text{ClO}_2^-$ , and  $\text{ClO}_3^-$  species in synthetic urine  
 720 matrix based on the application of the EO+ $\text{H}_2\text{O}_2$  process, at the current density of  $50 \text{ mA cm}^{-2}$ ,  
 721 for a period of 120 min (of electrolysis) (Figure 7). As can be observed, during the first  
 722 minutes of treatment, the initial pH of the synthetic urine was 5.26, and the matrix exhibited a  
 723 high concentration of chloride ions and a modest formation of  $2.7 \text{ mg L}^{-1}$  of  $\text{ClO}_3^-$  within the  
 724 first 10 min of electrolysis, with no  $\text{ClO}^-$  or  $\text{ClO}_2^-$  species detected. As the electrolysis time  
 725 progressed and the solution pH increased, there was a decrease in the chloride ions  
 726 concentration, while the concentrations of both chlorinated species increased. This rise in the  
 727 generation of chlorinated species points to the progressive conversion of chloride ions into  
 728 their oxidized forms - a phenomenon also reported in the literature [53,54]. After 45 min of  
 729 electrolysis, with a pH ranging between 6.39 and 6.60, the concentrations of  $\text{ClO}_2^-$  and  $\text{ClO}_3^-$   
 730 surpassed that of  $\text{ClO}^-$  and continued to exhibit a gradual increase until the end of the process.  
 731 On the other hand,  $\text{ClO}_2^-$  and  $\text{ClO}_3^-$  concentrations of 43 and 65  $\text{mg L}^{-1}$ , respectively, were  
 732 recorded at the end of the 120 min of electrolysis. These observations evidently reinforce the  
 733 presence of competition between the electro-generation of  $\text{H}_2\text{O}_2$  and the evolution of chlorine  
 734 species, particularly  $\text{Cl}_2$  and  $\text{ClO}^-$ , as demonstrated in Eqs. 17-22.

735 Notwithstanding the competition between the electro-generation of  $\text{H}_2\text{O}_2$  and the  
 736 evolution of chlorine species, the accumulated concentration of  $\text{ClO}^-$ , which was  
 737 approximately  $21 \text{ mg L}^{-1}$ , is found to be significant considering that  
 738 hypochlorite/hypochlorous acid acts as the primary mediator in electrochemical processes in  
 739 the presence of  $\text{Cl}^-$  [55]. Furthermore,  $\text{ClO}^-$  can be generated within a pH range of 3.0 to 8.0,  
 740 and the species is capable of reacting with organic compounds more rapidly than other species  
 741 due to its reaction homogeneity throughout the solution under treatment. In contrast, oxidation  
 742 facilitated by DSA ( $\cdot\text{OH}$ ), for instance, is restricted to the anode surface, as this species has a  
 743 very short lifespan [15]. Thus, during the EO+ $\text{H}_2\text{O}_2$  process, the organic compounds in  
 744 synthetic urine are expected to undergo simultaneous oxidization by both  $\text{H}_2\text{O}_2$  and  $\text{ClO}^-$ ,  
 745 with lesser contribution from DSA ( $\cdot\text{OH}$ ).

746 These findings allowed us to conduct a quantitative analysis that provided valuable  
 747 insights into the degradation of organic compounds in synthetic urine and their individual  
 748 contributions to the electrochemical process. The observed dynamics reflect the complex  
 749 interaction between direct and indirect oxidation involving  $\text{H}_2\text{O}_2$ , chlorinated species, and  
 750 hydroxyl radicals in the organic matter removal process.

751

### 752 3.6. Evolution of carboxylic acids and destination of nitrogen ions in the treatment of 753 synthetic urine under the EO+H<sub>2</sub>O<sub>2</sub> process

754

755 Given the importance of the mineralization process in synthetic urine matrices, a  
756 thorough analysis was conducted in order to identify and quantify the intermediate products  
757 derived from the treatment of 3,303.3 mg L<sup>-1</sup> of urea, 169.7 mg L<sup>-1</sup> of creatinine, and 50.4 mg  
758 L<sup>-1</sup> of uric acid (TOC<sub>i</sub> = 750 mg L<sup>-1</sup>) based on the application of the EO+H<sub>2</sub>O<sub>2</sub> process at the  
759 current density of 50 mA cm<sup>-2</sup>. Figures 8a and 8b show the time course of accumulated short-  
760 chain linear aliphatic carboxylic acids; these acids - with special reference to oxalic acid and  
761 maleic acid, were found to be significantly accumulated in the system during the treatment.

762 The initially high concentration of oxalic acid in the system (Figure 8a),  
763 approximately 88 mg L<sup>-1</sup> in 15 min, reflected a stabilization pattern observed throughout the  
764 process, with minimal fluctuations recorded up to the end of the 120 min of electrolysis. This  
765 behavior suggests that oxalic acid is rapidly formed and remains a stable intermediate,  
766 resisting complete mineralization in the synthetic urine matrix. Conversely, maleic acid  
767 (Figure 8a), which also began with a high concentration of about 440.0 mg L<sup>-1</sup> in 15 min,  
768 recorded a significant reduction in its concentration, reaching approximately 205.0 mg L<sup>-1</sup> in  
769 30 min, and subsequently stabilizing at around 230.0 mg L<sup>-1</sup>. This more pronounced  
770 fluctuation and the decrease in concentration compared to that observed in the first 15 min  
771 may be indicative of the partial transformation of maleic acid into other by-products or a  
772 subsequent deeper oxidation process. In contrast, formic and acetic acids (Figure 8b), which  
773 began being accumulated in a more modest fashion, saw a gradual increase in their  
774 concentration over the electrolysis time. Formic acid increased from approximately 3.8 mg L<sup>-1</sup>  
775 in 15 min to 14.8 mg L<sup>-1</sup> in 120 min, while acetic acid increased from 0.96 mg L<sup>-1</sup> in 30 min  
776 to approximately 4.7 mg L<sup>-1</sup> in 120 min. This progressive accumulation suggests that these  
777 acids (formic and acetic acids) are formed at a slower rate.

778 It is likely that acetic acid is derived from the cleavage of aromatic and conjugated  
779 rings [56], while oxalic and formic acids may originate from the oxidation of other long-chain  
780 carboxylic acids [57,58]. These results show that, despite the partial degradation of organic  
781 compounds in the synthetic urine matrix, the considerable accumulation of carboxylic acids as  
782 intermediates explains why a maximum mineralization of only 31.8% was obtained. This is  
783 evidenced by the remaining TOC content in the synthetic urine solution at the end of the  
784 process - approximately 504.0 mg L<sup>-1</sup> (see Figure 5c), of which about 24% was composed of  
785 carboxylic acids, primarily maleic acid, which corresponded to a TOC of 92.4mg L<sup>-1</sup>.  
786 Interestingly, despite their resistance to mineralization, literature reports indicate that these  
787 low molecular weight carboxylic acid species are considered innocuous and biodegradable  
788 [51,58].

789 Regarding inorganic ions, as expected, the main products detected were ammonium  
790 (NH<sub>4</sub><sup>+</sup>) and nitrate (NO<sub>3</sub><sup>-</sup>) due to the presence of urea (N = 1540.52 mg L<sup>-1</sup>), creatinine (63.03  
791 mg L<sup>-1</sup>), and uric acid (N = 16.81 mg L<sup>-1</sup>) in the synthetic urine composition; the presence of  
792 these products in the matrix resulted in a high total nitrogen concentration of 1620.4mg L<sup>-1</sup>.  
793 Nitrite (NO<sub>2</sub><sup>-</sup>) was not found in significant concentrations. As observed in Figure 8c, one can  
794 clearly see an increase in the concentration of NH<sub>4</sub><sup>+</sup> up to approximately 42 mg L<sup>-1</sup> in 15 min.  
795 From this time onwards, there is a decrease in NH<sub>4</sub><sup>+</sup> concentration, accompanied by a gradual

796 accumulation of  $\text{NO}_3^-$  which remains as the final product after 120 min of electrolysis  
797 (representing 2.77% of the initial N). These results suggest that the gradual conversion of  
798 ammonia to nitrate reflects the primary reduction of nitrogen to more oxidized species.  
799 Considering the contribution of urea, creatinine, and uric acid to the nitrogen content in the  
800 system, it can be inferred that the rapid accumulation of  $\text{NH}_4^+$  up to the first 15 min was  
801 mainly due to the rapid decomposition of uric acid. Furthermore, considering the initial  
802 nitrogen content and the fact that the final accumulated concentration of nitrogen ions did not  
803 exceed  $46.3 \text{ mg L}^{-1}$ , one can infer from a general mass balance that over 97% of the initial  
804 nitrogen content remained in the form of the original molecules of urea and creatinine, or was  
805 lost from the synthetic urine solution as volatile products such as  $\text{N}_2$  and  $\text{N}_x\text{O}_y$  [58].

806

#### 807 4. Conclusions

808 This study investigated the potential of using *in situ*  $\text{H}_2\text{O}_2$  generation in synthetic urine  
809 with GDE/PL6C as a decentralized electro-sanitation strategy. The initial results indicated  
810 that the *in situ* electro-generation of  $\text{H}_2\text{O}_2$  in  $\text{Na}_2\text{SO}_4$  solution, under the same pH and ionic  
811 strength of synthetic urine, directly correlates with the applied current density. The final  
812 results obtained showed that the application of a current density of  $25 \text{ mA cm}^{-2}$  generated  
813  $258.0 \text{ mg L}^{-1}$  of  $\text{H}_2\text{O}_2$ , which increased to  $958.0 \text{ mg L}^{-1}$  when the current density was raised to  
814  $100 \text{ mA cm}^{-2}$ . This outcome was attributed to an increase in the electron transfer rate at the  
815 electrode/solution interface. However, kinetic analysis suggested that at higher current  
816 densities,  $\text{H}_2\text{O}_2$  production did not follow a linear pattern; this points to limitations in the mass  
817 transfer process. The choice of using the current density of  $50 \text{ mA cm}^{-2}$  to investigate the  
818 performance of the system was justified by the fact that the proposed system required the  
819 application of a relatively high current density with economic viability which offers a balance  
820 between energy efficiency and energy consumption efficiency with high  $\text{H}_2\text{O}_2$  production and  
821 effective compounds degradation.

822 The analysis of  $\text{H}_2\text{O}_2$  production in synthetic urine revealed that the presence of  
823 organic compounds, such as urea, creatinine, and uric acid, in the synthetic urine matrix  
824 interfered with  $\text{H}_2\text{O}_2$  accumulation, and this resulted in a decrease of 65% in  $\text{H}_2\text{O}_2$  production  
825 compared to the concentration of  $\text{H}_2\text{O}_2$  generated in the aqueous solution containing only  
826  $\text{Na}_2\text{SO}_4$  (at the current density of  $50 \text{ mA cm}^{-2}$ ). This outcome was attributed to the  
827 consumption of  $\text{H}_2\text{O}_2$  in the degradation of organic compounds. Additionally, it was  
828 demonstrated that the ionic composition of urine further limited  $\text{H}_2\text{O}_2$  production, and this  
829 clearly reflects the complexity of the reactions involved. Energy efficiency analysis showed  
830 that the  $\text{Na}_2\text{SO}_4$  solution exhibited lower energy consumption and higher current efficiency  
831 compared to the synthetic urine matrix - both in the presence and absence of organic  
832 compounds, which exhibited higher energy consumption and lower current efficiency. The  
833 results obtained from these analyses show that the presence of inorganic ions in synthetic  
834 urine significantly affected the  $\text{H}_2\text{O}_2$  electro-generation efficiency. In particular, the presence  
835 of chloride and phosphate ions exerted a negative impact on  $\text{H}_2\text{O}_2$  electro-generation, by  
836 either competing with reagents on the electrode surface or promoting secondary reactions that  
837 consumed the  $\text{H}_2\text{O}_2$  generated.

838 Regarding the oxidation of organic matter in synthetic urine, the data obtained showed  
839 that the *in situ* generation of  $\text{H}_2\text{O}_2$  in the matrix enhances the degradation of complex organic

840 compounds, with increased efficiency in the removal of urea (8.3%) and creatinine (8.6%).  
841 Kinetic analysis pointed to the preference of the system for the degradation of uric acid; in  
842 essence, the results of this analysis highlighted the importance of chemical interactions in the  
843 degradation process. The mineralization of the organic compounds, although limited to 31.8%  
844 TOC removal, showed that H<sub>2</sub>O<sub>2</sub> may act as a complementary degradation agent in complex  
845 wastewater treatment systems. The high concentration of carboxylic acids, particularly oxalic  
846 and maleic acids, accumulated in the system was regarded as the primary intermediate  
847 products of the degradation process. Of the nitrogenous compounds formed in the oxidation  
848 process, we observed the initial release/formation of NH<sub>4</sub><sup>+</sup>, which was subsequently oxidized  
849 to NO<sub>3</sub><sup>-</sup>.

850 The findings of this study show that the *in situ* generation of H<sub>2</sub>O<sub>2</sub> is a highly  
851 promising alternative technique for the treatment of urinary effluents; this technique is found  
852 to promote greater energy efficiency and partial mineralization of organic compounds. When  
853 it comes to the treatment of complex matrices, it becomes evident that, in addition to organic  
854 compounds, one needs to also consider the complex nature of inorganic compounds.  
855 Understanding the specific role of each inorganic ion present in urine is essential for  
856 developing more efficient treatment techniques that are capable of optimizing the  
857 electrochemical process, while reducing energy consumption and maximizing current  
858 efficiency. This study not only elucidates the mechanisms involved in H<sub>2</sub>O<sub>2</sub> electro-generation  
859 in both organic and inorganic matrices but also provides significant contributions to the  
860 advancement of electro-sanitation technologies. Given the importance of these findings,  
861 future studies will focus on translating this knowledge to real urine matrices, further  
862 enhancing the sustainable treatment of decentralized wastewater systems and accelerating  
863 progress toward the accomplishment of SDG 6.

1080

### 1081 **Highlights**

- 1082 • Inorganic urine composition significantly influences *in situ* H<sub>2</sub>O<sub>2</sub> generation
- 1083 • Active chlorine species affect the accumulation of H<sub>2</sub>O<sub>2</sub> in urine
- 1084 • *In situ* H<sub>2</sub>O<sub>2</sub> generation enhances the removal of organic compounds in urine
- 1085 • Uric acid is degraded 95 times faster than urea and 15 times faster than creatinine
- 1086 • *In situ* H<sub>2</sub>O<sub>2</sub> generation contributes to sustainable treatment of sanitary effluents.
